President's Address.—Dr. THOMAS H. HALSTED delivered this address, in which he stated that at the time of signing the armistice 30,591, or 37 per cent., of the effective active practitioners of this country had given up their private practice and had left their homes in war service. In addition to these, 21,616 doctors were serving on medical examining boards and advisory boards, giving many hours daily or weekly to the important service of selecting and classifying the drafted men. If the war had continued another year, there would have been left at home to care for the civilian population less than a third of the usual number of doctors, and those doing this home work were either above sixty years of age or physically unable to stand the strain of military life. Had the medical profession of the world stood the test of efficiency in service when the great opportunity came to prove its worth in saving lives, shortening sickness, alleviating suffering, preserving limbs, returning the soldier to his home in as good condition physically as the ravages of shell, bullet, bayonet, mental strain, and infectious disease would permit? In answering this question Dr. Halsted said that the great causes of death among the wounded were infection and sepsis due to the streptococcus. Antitoxin against tetanus had saved the lives of thousands of wounded. The discovery of Dakin of the value of hypochlorite of soda for the killing of the organisms of sepsis and of Carrel's genius in devising the means of using Dakin's discovery marked a great advance in the treatment of septic wounds. This method, together with débridement, won the battle of medical science against sepsis, provided the wounds were brought out of shell hole and "No Man's Land" in time. It was only toward the end of the war that a serum was discovered that was effective against that horrible complication of deeply infected wounds, gas gangrene. The marvellous advance in lung, brain, abdominal, and joint surgery, made possible largely through the *x*-ray, saved thousands of lives which would have been hopeless in any previous war. The wonderful surgery of the genius Morestin, who literally worked himself to death in Paris, dying a few weeks ago at the age of forty-six years, and of other surgeons skilled in plastic surgery of the face, saved from a living hell any number of the victims of those most frightfully disfiguring of all war wounds. The transplantation of living tissue by Carrel and the still more advanced work of Nageotte and Sencert, whereby dead but sterile connective tissue, nerve, artery, tendon, etc., was transplanted successfully from animal to the living subject, opened a field of surgery the end of which almost staggered the imagination. That the percentage of deaths from battle casualties was not greater was largely due to the fact that medical science in the lager sense salvaged the wounded and saved them to their countries. More than eighteen million wounded soldiers survived their wounds, many of whom would not have been saved but for the combined victory of the surgeon and the medical laboratory and research worker. It was probably no exaggeration to say that the new surgery employed in the treatment of the wounded reduced the numbers of those who would have died, under the conditions of any previous war, by seven and three-quarters millions, the estimated number of soldiers who lost their lives in this war. Dr. Halsted cited statistics showing the extent to which deaths from disease had depleted the ranks of the armies of the different countries in modern wars. The Canadian Army had lost 94 per cent. of its dead soldiers from battle casualties and less than 6 per cent. from disease. That the United States did not have a record approaching this was due to the epidemic of influenza, and had the war continued for a year or two our record would probably have approached that of the Canadian Army. Such a record stood out in bold contrast to that of the Spanish-American War, during which typhoid fever caused 86 per cent. of the total deaths of the war. In a trench warfare typhoid fever and cholera would, under former conditions, have found most favorable elements for their development had not vaccination against these diseases, together with the efficiency of the Sanitary Department in protecting the drinking water of the army, been successful in preventing them. The discovery of the method of transmission of trench fever, which was causing more morbidity than any other disease, made the prevention of this disease a simple matter. This disease was rapidly being mastered at the time of the signing of the armistice. Another of the most serious causes of hospitalization and consequent reduction of man power in all the armies, as in previous wars, had arisen from venereal disease. So efficient was the prophylaxis against these diseases that they prevailed in the army to a much less extent than in civil life, being less than 1 per cent. in our army, as against that in other armies where this prophylaxis was not taken. Many other triumphs of medical science might be enumerated, but these served to show what surgical skill, sanitary science, and high-grade medical personnel, coupled together and operating under marvellous organization, saved, from what would have been certain death in any previous war, more wounded and sick soldiers than were killed in battle or died from their wounds and their diseases. It required little imagination to believe that 10,000,000 people, chiefly the best youth in the world, were alive to-day who would have been buried in the trenches in Europe but for the scientific progress in medical, surgical, and sanitary science of the past twenty-five years as applied to this war. The most valuable asset of any nation was its people. A celebrated actuary estimated the average capital value of a man in the six countries, United States, Great Britain, France, Germany, Russia, and Austria at $2,892. On this basis $28,920,000,000 worth of human life had been saved out of the wreck of the war by the late developments of medical science alone, a saving to the world almost equal to the total cost of the war to France or Great Britain and three-fourths that expended by Germany. The mere statement of such facts as these was sufficient to prove the wisdom of taking every precaution to care for the welfare of that most valuable resource of national wealth, human life. Yet, except in time of war, when the human unit was so essential, the nation took, as a government, comparatively little interest in this item of its wealth. It would seem that one of the first results of the coming readjustment in national government would be the addition to the great departments of a department of health with a seat in the Cabinet of the President. The duties of such a secretary would be, in a large way, to coordinate in it the various interests that were now scattered, to supervise national medical education, promote scientific medical and animal research and investigation, to guard the country against the increase and spread of endemic diseases, and doing those things which would tend to preserve health, prolong life, prevent disease and decay, safeguard child welfare, and promote the productive efficiency as well as the happiness of this valuable national human asset. Dr. Halsted made a plea for the standardization of medical education in the United States and said that until there was standardization there could not be reciprocal exchange of license and privilege among the states as there should be. The first part of the medical student's course was spent in the so-called scientific branches, anatomy, physiology, chemistry, bacteriology, pathology, and laboratory subjects taught by full time professional teachers, trained pedagogues, men who were specialists in their lines, and the result was satisfactory alike to the student and teacher and the subjects taught. It was in these subjects and by these men that the marvellous advances in scientific medicine had occurred, and it was to them most largely that the huge saving in life in the present war was more or less directly due. It was in the latter half of the medical course that failure in the medical course was most apparent. This was because of the system of volunteers and unsalaried teaching in the clinical subjects by men actively engaged in practice and selected, not always, with regard to their peculiar fitness and qualification for the chair. This volunteer system was apparently a good way of getting clinical teaching by medical colleges and universities for nothing, because the best service was not being given or received. This system was absolutely wrong. It was time for the medical

profession to cease carrying the burden which had become too great for it with all the modern advances and requirements. The clinical half of a medical course should be put on the university basis, like the first half, and when that was done there would be as great progress made in clinical medicine as had been made in laboratory medicine. The hospital would become the clinical laboratory. Teachers would be chosen because of their special qualifications, and if their work was unsatisfactory or inefficient they would be replaced. It was within the truth to say that no man in this country, or perhaps in the world, had ever seen in his own lifetime such reward for money well invested as John D. Rockefeller, who through the scientific labors of medical scientists working in the Rockefeller Institute in New York, had made such discoveries in the causation and treatment of disease that literally millions of men in the world owed their lives and health to investigation conducted in that medical research laboratory.

Oration. The Doctor and the Changing Order.—George B. Vincent, president of the Rockefeller Foundation, delivered an address in which he said, in part, that he was not a Doctor of Medicine, but a Doctor of Philosophy, so he hoped they would have forbearance with him if not patronage for him if he diverted their minds from exacting and scientific pursuits to a little philosophy. He dwelt in humorous vein on the power of a popular phrase as a substitute for thinking, and of the influence of phrases in moulding the philosophy of a people. Even a phraseology which no one could understand had its influence. The legal profession had a bewildering phraseology which no one but a lawyer could understand and even the medical profession could not prove an alibi; it had many phrases ending in "itis," some of which were not only incomprehensible and bewildering, but even fatal. He went on to show that in the phrases of a people one could find their crystallized philosophy of life. In the pioneer days of our national history were found such phrases as "paddle your own canoe," "look out for number one," "let every tub stand on its own bottom," "America, the land of opportunity." These were the phrases that marked the individualistic philosophy of life where everyone was for himself. In that period the "jack of all trades" was exalted and there was no place in a community for the man who knew more than his fellows (in fact, it was still an indivious distinction to know more than someone else). In those days there were no organized charities. If a man was in need his neighbors took it as a matter of course that they should help him. If there was sickness in a family the neighbors came in and nursed the patient and the patient often survived. Under the conditions of those days the individualistic philosophy had its place and worked, but there came a time when the country was no longer all frontier, when the fact that a man failed to get along was not due to a lack of effort on his own part, but because of industrial and market conditions. There came a time when we needed a new set of phrases and we began to hear such phrases as "social organization," "interdependence," "social justice," "brotherhood," "social welfare" and finally "service," a phrase so overworked that one almost hated to use it, because this coin had been handled until it was worn so smooth that one could scarcely see the inscription. People began to ask what these phrases meant, until finally they had come into our national life. Dr. Vincent alluded to conditions in colonial times to show that at that time the people of one section of the country did not understand those of other sections, and showed how we had developed a national solidarity which we did not fully understand until it was revealed to us by the war. He said he had not mentioned reconstruction because he believed more in evolution and in growth than in the sudden making over of society. He believed that everything that happened was the outcome of what had gone before. One who had studied the situation could have seen the French Revolution coming on for a hundred years before it actually occurred. The occurrence of the recent war was inevitable from the time Germany took Alsace-Lorraine. There was no unexplained sudden force through which society was developing, but a constant change of relationships; religious, social, economic changes had been going on for a long time and the war had only accelerated them. One of the great things the war had done was to reveal America to herself. We had been afraid that in case of war the foreign people that were here would side with the countries from which they had come. The war had shown us the solidarity of the American people. We had also discovered much illiteracy. We found, too, that many people speaking foreign languages were isolated from those among whom they were living. As to the relation of the medical profession to the changing conditions of the present time, they should prepare to adapt themselves to these changed social conditions. There were three ways of looking at the present situation. The first of these was an attitude of alarm and a conviction that things were worse than they were in earlier years. A second way was to see a possible complete social transformation which was to be easily brought about. He could not quite sympathize with this view, but thought the third way of appraising the situation, namely, the Greek golden mean, was perhaps the most rational. We should go loyally and courageously forward meeting the new situation with a new philosophy and new phrases. The doctor faced an entirely new situation from that of ten years ago. New knowledge and new discoveries had accumulated so rapidly that it was impossible for any one man to keep up with them. Specialism was the only solution. The physician was becoming less and less able to perform his work efficiently, independently. The cooperative clinic was already being operated successfully. A maternity clinic in Boston was so conducted that the mother received prenatal care, medical service at the time of the birth of the child, and after care, all for an inclusive fee. There were also the infant welfare, tuberculosis and venereal clinics. As to health insurance Dr. Vincent said that his mind was open. He spoke hopefully of the possibility of developing some plan that would protect the industrial population against pauperism and social dependence and which would preserve their dignity and enable them to maintain their status in the democracy. It would be necessary to learn to conform ourselves to new social ideals in order to perform our function to society and to be a part of the common life. In closing, Dr. Vincent congratulated the medical profession on its achievements in the past and described in eloquent terms the vista of service that was opening up before them.

Virginia State Board of Medical Examiners.

Richmond, June 18-21, 1918.

(*Continued from page* 718.)

THEORY AND PRACTICE OF MEDICINE.

1. Describe a typical case of measles, giving periods of incubation and contagion, symptoms, complications, and treatment.
2. Give clinical picture of chronic gastric ulcer.
3. Discuss the subject of asthma from standpoint of etiology and treatment.
4. Give clinical symptoms and physical signs of chronic cardiac dilatation.
5. Name the two varieties of jaundice and give two examples of each variety.
6. Define monoplegia, paraplegia, ataxia, tic (simple.)
7. Diagnosis, course, prognosis, and therapeutics of acne vulgaris.
8. Define obesity and give in detail treatment of a case.
9. Name the three clinical forms of myxedema.
10. Treatment of acute nephritis.

EMBRYOLOGY AND OBSTETRICS.

1. What are the functions of the corpus luteum?
2. Describe the embedding of the ovum in the uterine mucous membrane.
3. Give four most valuable signs of pregnancy at the sixth or eighth week.
4. Give the functions of the liquor amnii.

5. Give the proper management of a normal case of labor from beginning to end.
6. How would you know that the relations between the child's head and the mother's pelvis were normal?
7. Give the normal mechanism of the expulsion of the placenta.
8. Give three causes of retained placenta.
9. Make a differential diagnosis between caput succedaneum and cephalhematoma.
10. How does rickets cause a flat pelvis?

ANSWERS.

THEORY AND PRACTICE OF MEDICINE.

1. MEASLES.—*Symptoms:* "After an incubation period of from ten to fourteen days the disease is manifested by a chill or chilliness, fever ranging from 101° to 102° F., muscular soreness, headache, and intense nasal, pharyngeal, and laryngeal catarrh. There are present also intolerance to light, redness and watering of the eyes, sneezing, and coughing. On the second day the fever remits to rise again on the fourth day, when an eruption of small, dark red, velvety papules arranged in crescentic groups appears on the face and soon spreads over the entire body. The catarrhal symptoms still persist. The eruption is attended by itching and more or less burning, and about the ninth day begins to fade and disappear entirely by bran-like desquamation. All the symptoms then gradually ameliorate. Koplik's spots (a peculiar eruption consisting of small, irregular spots, of a bright red color, with a bluish-white center, which appear on the mucous membrane of the lips and cheeks on the first day of invasion) are said to be pathognomonic.

"*Complications:* Catarrhal pneumonia and gastro-enteritis; as sequels may be mentioned tonsillitis, tuberculosis, ophthalmia, and cancrum oris. With regard to *contagion:* A child who has been exposed to infection should not be allowed to go to school till sixteen days have elapsed since last exposure; one who has had measles should not be allowed to return to school till one month after the onset of the symptoms and if there are no discharges and no sequelæ.

"*Treatment:* Isolation, rest in bed, and protection from drafts and from bright light are necessary from the onset of the disease. It is often desirable to give a diaphoretic mixture. The bowels should be kept regular by means of some mild laxative. The diet should be semisolid. Mild cases require no medicines. Cool sponging or the following will reduce the temperature when it becomes alarmingly high:

℞ Tinct. aconiti.....mxij to iv
Spts. ætheris nitrosi.....mxx to xv
Liq. potas. citrat. q. s. ad f 3j

M. S.—Every two hours.

"Daily inunction of cold cream, cocoa-butter, eucalyptol in petrolatum, and similar oily substances will serve to relieve the itching of the eruption. Camphorated oil rubbed on the chest and applied to the nose and neck aids in lessening the catarrhal symptoms."—(Hughes' *Practice of Medicine.*)

2. *Gastric ulcer* is generally caused by injury or bacteria, is most apt to occur between the ages of twenty and forty-five; after eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents shows an excess of free HCl.

3. *Asthma* is a paroxysmal expiratory dyspnea. It is supposed to be due to a diminution in the caliber of the smaller bronchial tubes; the cause is unsettled. It generally comes on suddenly at night; patient sits at open window or seeks the air; expiratory efforts are violent; there is wheezing, pale or livid face, anxious expression. Speech is impossible, pulse small and feeble, may last from a few minutes to several hours. Never fatal by itself.

Asthma may occur as a symptom in cases of chronic nephritis (*renal asthma*), or in chronic heart disease (*cardiac asthma*); it may also be caused by the action of the pollen of certain grasses or plants on a particularly sensitive respiratory mucous membrane (*hay asthma*); certain irritants may also cause the condition (*bronchial asthma*).

Treatment of hay asthma: Any existing nasal trouble must be found and removed or otherwise treated; a change of climate is often beneficial, a sea voyage or a sojourn in a mountainous district being of service; tonics, such as strychnine, quinine, or arsenic, should be administered before and during the attack; the eyes may be washed with a solution of boric acid (about 1:50); the application of Dobell's solution in the form of a spray or of adrenalin solution (1:5000) on pledgets of cotton has also been recommended. Some have also advocated the treatment by antitoxic serum or pollantin.

Other remedies of asthma include emetics, the nitrites, iodide of potassium, belladonna and stramonium, pilocarpine and adrenalin.

4. CARDIAC DILATATION.—"*Inspection* detects enlargement and distention of the superficial veins and an indistinct, often wavy and diffused, cardiac impulse. If tricuspid regurgitation is present, jugular pulsation will be observed. *Palpation* confirms inspection; the impulse is feeble, irregular, and heaving. *Percussion* serves to determine extension of the area of cardiac dullness transversely, and especially toward the right side. *Auscultation* in the presence of valvular lesions reveals characteristic murmurs. If there are no valvular lesions the cardiac sounds are weaker than normal and the first sound is sharper in quality than usual."—(Hughes' *Practice of Medicine.*)

5. VARIETIES OF JAUNDICE.—I. *Obstructive:* (a) Due to foreign bodies within the bile-ducts; (b) due to stricture or obliteration of the duct. II. *Non-Obstructive:* (a) Due to specific fevers; (b) due to poisons.

6. *Monoplegia* is paralysis of one limb only.
Paraplegia is paralysis of the lower extremities.
Ataxia is lack of coordination in muscular action.
Tic is a twitching or spasm of one or more muscles.

7. *Acne vulgaris* is an inflammatory disease of the sebaceous glands characterized by papules and pustules, and usually situated on the face or back. There is an aggregation of small papules, pustules, and comedones about the face, chest, and shoulders. Pustules or papules predominate according as the disease is acute or chronic. New lesions develop as the old disappear, so that the disease usually runs a protracted course. Subjective phenomena are absent. The distribution, the chronic character of the affection, the involvement of the sebaceous glands, and the association with comedones are the diagnostic features which separate acne from all other affections. The disease is curable, but is rebellious to treatment and prone to relapse. The general health must be improved. The diet should be nutritious, but easily assimilable; rich food must be prohibited. Constipation should be relieved by mild laxatives. In the anemic and debilitated, iron, quinine, strychnine, and cod liver oil are useful remedies. The special drugs which have been recommended are arsenic and calx sulphurata. Arsenic is best suited to the sluggish indurated forms; the calx sulphurata (1/10 to 1/6 grain four times daily) to the pustular variety. Vaccine treatment, especially the conjoint use of the *Bacillus acne* and the *Staphylococcus albus*, is sometimes useful. In the acute form mild applications should be employed, like the following calamine lotion:

℞ Pulveris zinci oxidi.....3iij
Pulveris calaminæ.....3ij
Glycerini f3j
Aquæ calcis.....f3vj.—M.

In chronic cases the sebaceous plugs should be removed by a watch-key and the pustules incised. Thorough washing with very hot water and green soap is also advisable. The best local remedies are sulphur, mercury, and resorcin.—(From Stevens' *Practice of Medicine.*)

8. OBESITY is a disorder of metabolism characterized by the excessive deposition of fat in the tissues. *Treatment:* "The essence of successful treatment consists in bringing the diet within the requirements of the body as regards heat and energy, and in promoting oxidation and the destruction of fat by carefully regulated and graduated exercise, massage, and baths—all of which must be carefully supervised on account of the frequency of associated cardiac weakness. There are several systems of dietetic regulation, of which

the best known are Ebstein's, Oertel's, von Noorden's, and Banting's (for details of which one may refer to special treatises). In general, however, the amount of food should be reduced, especially the starches and sugars; the fluid intake should be greatly restricted, and the small amount (two to three pints daily) allowed should be taken preferably two hours after meals than with food; alcohol should be prohibited in most cases. Care should be taken to see that the nitrogen output does not exceed the intake, since this (destruction of the body protein) is answerable for most of the weakness that attends many 'cures.' Medicinal treatment is of secondary importance; a weak heart sometimes has to be stimulated, general weakness suggests the use of tonics, anemia requires the use of iron, etc. Thyroid extract is sometimes of service, but it must be employed with caution, since it leads to breaking down of the body protein as well as fat, and may induce thyroidism in those ill able to withstand its effects."—(Kelly's *Practice of Medicine.*)

9. *The three clinical forms of myxedema* are: (1) Myxedema of infants or children—cretinism; (2) spontaneous myxedema of adults; (3) post-operative myxedema.

10. *Treatment of acute nephritis:* "The patient should be placed at rest in bed until all the symptoms have disappeared. A strictly milk diet is most suitable, but if the depression and weakness are marked, animal broths, and even oysters may be allowed. Tea, coffee, beef-tea extracts, and stimulants should be interdicted. Water or cream of tartar lemonade may be freely used for its diuretic effect. Dry cups should be applied over the kidneys, followed by digitalis or jaborandi poultices, using equal parts of flaxseed and the leaves of digitalis or jaborandi. The bowels should be kept freely opened by means of the saline cathartics, compound jalap powder, ʒi, in water before breakfast, or elaterium, gr. 1/6, repeated as the occasion requires. Combined with these procedures there should be free sweating or diaphoresis. This is best obtained by the use of the hot-air bath, the hot pack, or the wet sheet and blanket bath, stimulating the peripheral circulation after free sweating has occurred by rubbing with alcohol and water. Drugs may be administered coincidently to aid the sweating process. Spirit of nitrous ether, ♏v to xxx, fluidextract of pilocarpine ♏v to xxx, every three or four hours, pilocarpine hydrochloride, gr. 1/6, hypodermically, as the occasion requires, or the wine of ipecac, ♏i to iii, every half-hour may be used for this purpose. Diuretics, such as digitalis, digitalin, gr. 1/100, citrated caffeine, gr. ii to iv, or sparteine sulphate, gr. ⅓ to ½, should be employed. The onset of uremia calls for special treatment. As soon as the blood disappears from the urine some preparation of iron, preferably Basham's mixture, should be administered until the health is entirely restored. The addition of 1 minim of spirit of nitroglycerin to each dose of Basham's mixture increases its efficiency."—(Hughes' *Practice of Medicine.*)

EMBRYOLOGY AND OBSTETRICS.

1. *Functions of the corpus luteum:* During pregnancy it is concerned in the formation of the uterine decidua and the fixation of the fertilized ovum to the wall of the uterus; it is also concerned in the development of the mammary gland and the secretion of milk.

2. *Embedding of the ovum in the uterine mucous membrane:* "The generally accepted view is that the ovum penetrates the mucosa like a parasite through an opening which it makes for itself. The maternal tissues are probably dissolved by the action of ferments secreted by the trophoderm. The ferments affect not only the epithelium but the connective tissue and endothelium of the bloodvessels of the stroma. The cavity thus formed in the mucous membrane of the uterus therefore contains the blastocyst and a large amount of maternal blood which has escaped from the invaded vessels. The invasion of the maternal bloodvessels by the trophoderm results in the essential character of a placenta of the hemochorealis type, namely, that the superficial embryonic tissue (chorionic ectoderm, trophoderm) comes in direct contact with the maternal blood. Implantation usually occurs either on the posterior or anterior wall of the uterus and determines the situation of the placenta. It probably does not take place in a gland but between glands. The cause of penetration of the uterine mucosa by the ovum remains undetermined. It is assumed, however, that ameboid activity of the superficial cells of the trophoderm is at least one of the prime factors."—(Cragin's *Obstetrics.*)

3. Pregnancy cannot be diagnosed at the sixth or eighth week. The four most valuable signs at this time are: Cessation of menstruation, morning vomiting, changes in the breasts (enlargement, firmer, and more distended to touch, increased pigmentation and elevation of primary areola, and enlargement of Montgomery's tubercles), and softening of the cervix.

4. Functions of the Liquor Amnii.—(*a*) *During pregnancy:* (1) As a protection to the fetus against pressure and shocks from without. (2) As a protection to the uterus from excessive fetal movements. (3) It distends the uterus and thus allows for the growth and movements of the fetus. (4) It receives the excretions of the fetus. (5) It surrounds the fetus with a medium of equable temperature, and serves to prevent loss of heat. (6) It prevents the formation of adhesions between the fetus and the walls of the amniotic sac. (7) It has been supposed, by some, to afford some slight nutrition to the fetus. (*b*) *During labor:* It acts as a fluid wedge, and dilates the *os uteri* and the cervix; it also slightly lubricates the parts.

5. *The patient* should receive a full bath before labor begins and all bed clothing and personal clothing should be clean. If there are any pathological discharges from the genitals, the vagina should be thoroughly scrubbed with tincture of green soap and hot water, followed by a mercuric chloride douche (1:2000); this followed by a douche of sterile water. The physician's hands should be scrubbed for ten minutes with tincture of green soap and hot water, followed by alcohol, and immersion in mercuric chloride (1:1000). All instruments should be boiled for ten minutes or immersed in mercuric chloride (1:1000) for half an hour. Examinations should be made when necessary to determine the position, presentation, size of fetus, etc.

During the first stage a rectal enema of soapsuds with turpentine (ʒi) should be given, and when the os is dilated to the size of a silver dollar, the patient should be placed in bed, lying upon the side toward which the fetal back looks. If the pain is severe, chloral hydrate (gr. 15) may be given every half-hour for three doses.

During the second stage examinations should be made only when necessary. In multiparæ, the membranes may be ruptured with the finger or with some aseptic instrument. Care should be taken not to injure the child's scalp or the lower uterine segment. The pain may require the administration of chloroform or ether, but not to the extent of complete anesthesia. The expulsive force of the abdominal walls may be increased by directing the patient to pull upon a sheet firmly secured to the foot of the bed. Attempts may be made to prevent the laceration of the perineum by making firm backward and upward pressure against the occiput during the pains; by restraining voluntary expulsive efforts during the pains; and by securing expulsion of the head between the pains. The head should be supported when born; the eyes should be cleansed with sterile water; and if the cord is coiled about the neck, it should be loosened or slipped over the head. Delay in delivery of the shoulders may be overcome by stimulating the uterus by friction through the abdominal wall or traction. The cord is ligated and cut when pulsation has ceased, and the child is placed by the mother's side with its face turned away from the maternal discharges.

During the third stage ʒi of fluidextract of ergot is administered and irritation of the uterus by friction through the abdominal wall is practised for ten to fifteen minutes. If the placenta is not expelled by this time, the uterus is firmly grasped between the thumb and four fingers and compressed. Firm pressure is then made from above downward and backward in the direction of the pelvic canal. This usually causes delivery of the placenta. A vulvar pad of salicylated cotton and carbolized gauze and an abdominal pad and binder are then applied.—(*Pocket Cyclopedia.*)

6. If the patient is of normal stature, is not lame, does not give evidence of rickets or other bone disease, does not have a pendulous abdomen, and pelvimetry demonstrates normal measurements, it may be inferred

that the relations between child's head and the mother's pelvis are normal. Further, if internal examination shows that the fetal head is engaged in the pelvic brim at the first stage of labor, and that it has a tendency to descend with successive uterine contractions and pains, this inference is strengthened.

7. *Expulsion of the placenta:* "In most cases this follows directly upon separation. Two methods of expulsion are known, and it is still rather an open question which is the more common. The first is generally known as Schultze's method. In this the placenta is expelled like an inverted umbrella, the fetal surface coming first, and the membranes trailing behind. Where there has been the formation of a large retroplacental clot, this mechanism is probably common. The second method is usually known by the name of Matthew Duncan's. In it the lower edge of the placenta is first extruded and the whole organ slides down folded longitudinally upon itself."—(Johnstone's *Manual of Midwifery.*)

8. *Three causes of retained placenta:* Inertia uteri, endometritis, and morbid adhesion of the placenta to the wall of the uterus.

9.

CEPHALOHEMATOMA.	CAPUT SUCCEDANEUM.
This is a bloody effusion beneath the pericranium.	This is a serous effusion in the epipericranial tissues.
Develops two or three days after birth.	Present at birth.
Usually localized at the sides of the head.	Always over the presenting part.
Generally due to pressure.	Due to lack of pressure.
At first soft and cystic to the touch; later crepitant.	Soft, non-fluctuating.
Persists for a week or two, and may suppurate.	Disappears in two or three days.

10. *Rickets cause a flat pelvis,* as follows: "During the process of growth the lack of lime salts peculiar to the disease results in an abnormal softening of the bones, which, in consequence, yield more readily to the forces acting upon them. Extreme distortion of the pelvic bones may thus be produced. The pressure of the superimposed body upon the softened sacrum results in excessive bowing of the latter, with exaggerated prominence of the promontory and a marked decrease in the vertical height. There is a backward bowing of the vertebral column, as a result of which the body weight is directed from above downward and from behind forward; the pelvic crests are flared outward, and there results an upward and anterior inclination of the iliac fossæ, together with a marked separation of the anterior superior iliac spines, whereby the relationship existing between the intercristal and interspinous diameters is materially altered, the dimensions of the two being approximated. The obliquity or inclination of the pelvis is also increased, as in all forms of obliquely-contracted pelves; this induces greater traction upon the ligaments attached to the ischial tuberosities, and as a result these tuberosities are drawn outward and the pelvic outlet thereby increased in size. The pressure from below transmitted through the femora drives out the softened innominate bones, thereby increasing the width of the pelvis; this increase, however, is more than compensated for by the underdevelopment of the entire pelvis that characterizes the disease. The sacrum shows imperfect development of its alæ and thus contributes to the narrowing of the pelvis; as a consequence, the posterior surfaces of the iliac bones approach each other, as shown by an approximation of the posterior superior spines. In addition, all the articulations participate to a varying degree in the epiphyseal thickening."—(Dorland's *Obstetrics.*)

(*To be concluded.*)

Mortality from Grippe in Bordeaux.—Davezac has shown that in this city which should house a population of 300,000, the total deaths from influenza during the months of August, September and October amounted to but 481.—*Journal de Médeciñe de Bordeaux.*

Miscellany.

Professor Bernheim.—Doctor Blum in *Le Progrès Médical* for February 15 gives an appreciation of the lately deceased authority on suggestion. He was a great clinician and medical philosopher whose fame was world wide. Physicians from all parts of the habitable world have made pilgrimages to his clinic at Nancy. Here they were welcomed by a man of such simplicity and modesty that to the theatrical technique of many celebrities was formed an unusual and not unpleasant contrast. His notes were always dictated at the bedside and for 40 years he maintained this custom without interruption. Every morning found him in the hospital at 8 and there he remained until noon. On many days he returned later to watch an interesting or serious case. Bernheim as a result of these efforts was able at an early day to give a scientific foundation to psychotherapy and his priority in this field is undisputed. His hysteria however was not the phenomenon studied in the Salpêtrière before the eighties of the last century. A controversy between the two viewpoints developed and persisted for years: Bernheim, at first in the position of a rank outsider, predicted that his opponents would in time come to accept his views and this prophesy has been realized. We have not space to reproduce the essentials of the controversy but Bernheim's treatment has been summed up in the term *desuggestion,* which at the same time throws light on his conception of hysteria. Commonly reputed as a hynotist he was in reality a believer and practitioner of suggestion in all forms and of persuasion and reasoning in proper cases. For him sickness was not imaginary but visualized by imagination. But he was far more than a psychotherapeutist for he wrote lucidly of typhoid fever, aortitis, cardiac asthma, uremia, grippe, and many other organic affections, and first of all he was a traditional physician and well able to understand where suggestion begins to enter as a factor in pathogenesis. His last years were saddened by his own illness and by the war. One of his latest works, "Automatism and Suggestion," was written for psychologists. His best known rival Liébault supplied observations but Bernheim furnished their rationalization.

Mortality of Holland in 1918.—The deaths in the Netherlands for 1918 amounted to 115,426 as against 87,473 for 1917. These figures correspond respectively to 17.06 and 13.12 per 1000 inhabitants. Death rates in individual provinces vary greatly, from as high as 21 to as low as 12. These discrepancies do not accord well with the view that influenza was responsible for the great increase in deaths in 1918. It is a fact, however, that the provinces with the highest mortalities were the worst ravaged by the pandemic. But the high death rate was more than offset by the extremely high birth rates of the past two years—167,622 in 1917 and 173,112 in 1918. The exact number of deaths from influenza in 1918 was 17,744, but of this number only 8527 death certificates were worded "Spanish influenza." In 1917 the total number of deaths from influenza was but 453.—*Nederlandsch Tijdschrift voor Geneeskunde.*

A CASE OF OSTEITIS DEFORMANS.*

BY ALBERT WARREN FERRIS, A.M., M.D.,

WATKINS, N. Y.

RESIDENT PHYSICIAN, THE GLEN SPRINGS.

N January, 1913, there came under my care a lady ged about fifty-five years, suffering from pains in arious joints, showing great difficulty in sitting nd rising, and walking with a waddling gait. She ave a history of "rheumatic pains" in 1907, sup- osed to have been due to "sleeping in damp heets," but on second thought ascribed to a fall he suffered while walking in the mountains early hat summer. During that year she went to urope, where she drank Vichy water in such large uantities that she became very thin. On her re- urn her physician found her "perfectly healthy," he reports, but put her "on a diet for rheumatism," hereupon she regained her lost flesh. In 1910 she egan to have pain occasionally in both knees, and oticed that her legs were becoming bowed. She ent for treatment to a Spa, where she was told he had rheumatic gout and was treated without nprovement during the winter of 1910-1911. On eturning, she and her family noticed that her face ad altered; her temples had become sunken, and er head somewhat triangular. Various treatments ere instituted, without affording her any relief. uring the years 1911-12 her femora and some her bones acquired a decided curve. During 1912 ain appeared in her wrists and elbows, and lately he had experienced nocturnal pain in the left hip- int.

Besides the joint and bone pains and the increas- g disability, she complained on admission of a urning feeling in the stomach, with regurgitation gas and some cough, all of which symptoms ielded promptly to treatment with an alkali. She mplained of no other symptoms besides those oted.

Examination and brief study of her condition re- ulted promptly in a diagnosis of "osteitis defor- ans," which is so rare a disease that I make bold report it.

Our first accurate knowledge of the typical char- teristics of this malady was communicated to the edical world in 1877, when a case was presented the Royal Medico-Chirurgical Society of London Sir James Paget, who proposed the accepted me of the disease. Earlier cases than his, among em that of Wrani of Prague in 1867, were re- ported by Sir James. But his thorough knowledge and scientific presentation of the matter resulted in the disorder being called "Paget's disease" quite as often as "osteitis." A thoughtful and exhaustive paper was published in the *American Journal of the Medical Sciences* for November, 1901, by Packard, Steele, and Kirkbride, in which one hundred alleged or possible cases were considered, with the result that the authors rejected all but sixty-seven, reported previously to their own, thus presenting a

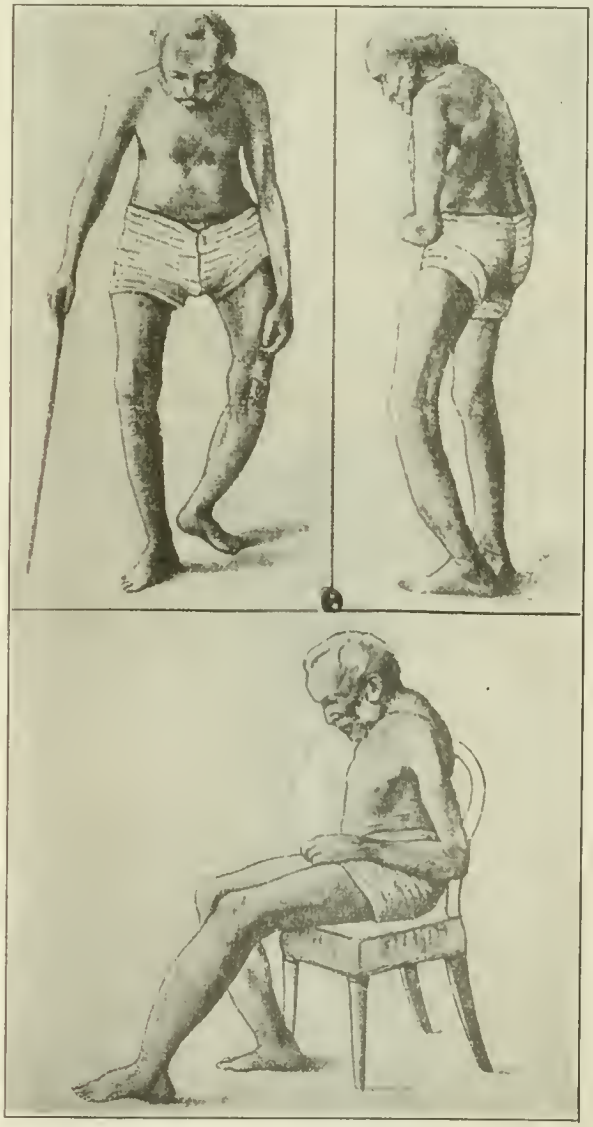

FIG. 1.—Case of osteitis deformans reported by Sir James Paget of London in 1876.

*Read at a meeting of the Fourth District Branch the Medical Society of the State of New York.

total of sixty-eight in the medical literature, to that date. In the MEDICAL RECORD for December 28, 1912, Fosdick Jones of Denver reported a case; and in the course of his article, which concludes with

FIG. 2.—Case of oesteitis deformans, reported by Dr. Arthur W. Elting of Albany in 1901.

an admirable bibliography, he states that so far as he is able to ascertain there were but twenty-six cases reported in this country since the publication of the résumé of Packard, Steele, and Kirkbride.

FIG. 3.—Right ulna and radius in author's case.

In the cases tabulated by the authorities mentioned, enlargement of the head was the first symptom noted in fourteen cases, enlargement of both tibiæ first in thirteen cases, enlargement of the left tibia the first symptom in eleven cases. In fifty of their cases the bones of the skull were involved, while in forty-seven both tibiæ were involved, and in forty-one both femora. Of their sixty-eight cases, forty-two occurred in males, twenty-six in females. Their oldest patient was aged seventy-three at the time of coming under observation; their youngest thirty-nine years. Eleven had definite symptoms at forty years or prior to that age. The average age on observation and diagnosis was sixty-one years. The disease appears to be one attacking people in middle life; although Elsner of Syracuse reported a case occurring in a girl of seventeen years, while Sonnenberg reported one case in a girl of sixteen. The oldest case on record is reported in *Virchow's Archiv* by Stilling, in 1890. This instance occurred in a woman ninety-two years old.

Those who have observed this disease agree in

FIG. 4.—Left knee from inner side in author's case.

reporting that the general health of the patient is rarely impaired. Even when the cranial bones are attacked and thickened there are no brain symptoms referable to the malady. All patients complain of pain, varying in severity, located in the affected bones, and generally of a rheumatic or neuralgic character. The longer bones are usually first affected, as in my case, particularly those of the lower extremities, which the weight of the body would seem to determine. Next in order the changes in the skull are noted, and then in the upper extremities. Probably next in order come the changes noted in the spine, consisting of a marked forward flexion with shortening of the vertebral column. The neck becomes flexed and the head inclines forward, or more often is dropped somewhat and approaches the chest. The joints seem to be rarely involved, though in consequence of the bowing of the lower extremities the knees

and ankles are often very painful, and walking is difficult.

Many theories have been advanced in former years as to the origin of the disease, and cancer,

Fig. 5.—Left femur from the rear, in the author's case.

rheumatism, syphilis, arteriosclerosis, and trauma have all been assigned in turn as the cause. At present these are not associated with the etiology, though in a few cases carcinoma has been intercurrent and the other diseases named have occurred in some patients. In a few cases in which extreme deformity of the thorax resulted, emphysema of the lung, pleural effusions, and even pneumonia have complicated the disease. Abdominal distress has been complained of by some patients in whom the alteration in position of the spinal column has resulted in a lozenge-shaped abdomen, a transverse suclus running across the soft parts, and in a broadening of the pelvis.

As to the pathology, von Recklinghausen advanced the theory that the disease started as a true osteomalacia, associated with inflammatory processes, leading to the transmission of medullary substances into fibrous tissue over which new bone grows. For there appears first to be an inflammatory condition associated with absorption of the bone, with later a hyperplasia of new bone, a marked thickening and irregularity of contour resulting, subsequently to the bending or bowing of the bone which has taken place during the earlier stage. The earliest pains are probably due to a stretching of the periosteum, caused by the deposit of inflammatory products and of new bone beneath it, while the later pains seem largely to be due to distortion of the joints, from alteration of the axes of bones, and the resulting partial displacement of the joint surfaces.

I have alluded to the earliest distortions noted by my patient. Examinations reveal the following anatomical changes:— The chin drops a little on the chest. The bones of the skull form a much larger proportion of the cranium than they should, as compared with the bones of the face. The frontal bone overhangs the face, though it is but fair to say that the patient claims this is a family trait, although not appearing in the case of her sister, who was also my patient. The curves of the clavicle are decidedly increased. The arms are relatively too long for the body, and are both deformed, being curved with an inward convexity. The left forearm is somewhat deformed, both radius and ulna being curved as shown in the skiagram. There is dorsal kyphosis, but no scoliosis. The pelvis is not noticeably enlarged, and its brim is not everted. The glutei are quite prominent, but very flabby, showing decided atrophy. The trochanters are not higher than normal, and the necks of the femora are not horizontal—a fact noted in a large proportion of the cases reported. Both femora are curved, the left much more than the right, the convexity being outward and forward. The left tibia is also more involved than the right. The patient is two inches shorter than she was four years ago.

Standing with heels together, the distance between the internal malleoli is 2.4 cm.; while between the internal condyles of the femora the distance is 18 cm. The bowing outward is most evident in the left femur, and least evident in the upper portions of the tibiæ.

On palpation the femora appear slightly enlarged throughout, the left trochanter being somewhat thickened. The circumference of the leg at the condyles is 43 cm. on both sides. The tibiæ show enlargement of both heads and the shaft of the

Fig. 6.—Left knee and tibia from the rear, in the author's case.

left, the right bone being slightly roughened and the left much roughened, both being irregular on the surface. The right fibula is bowed. There is no tumor formation.

External rotation and abduction of the femur is good on the right side, restricted on the left. Adduction, abduction, and rotation at the hip joint are normal. Flexion of either knee joint is somewhat difficult. The scapulæ present no abnormalities. The left humerus appears straight and not thickened at the surgical neck, though the skiagram shows an irregular contour with thickening of the upper and lower thirds of the shaft. The right radius appears normal, the left being bowed somewhat outward, as is also the left ulna. No abnormalities of the bones of the hands or feet were discovered.

The muscles of the thighs were not atrophied, nor were those of the legs or chest. The muscles of the arms were somewhat atrophied, and also the supraspinatus and infraspinatus were noticeably wasted. I have already noted the atrophy of the glutei.

The knee jerk was diminished on both sides; there was no clonus; there was no Babinski reflex.

The measurements of the skull resulted as follows:— From glabella to occipital protuberance the distance was 37 cm. The biparietal diameter was 16½ cm. The circumference of the skull was 56½ cm.

As the patient complained of increasing disability and a feeling as if her left lower extremity were bending under her, the treatment I instituted consisted of the lactophosphate of lime, iodide of iron, and alkalies to relieve her hyperchlorhydria; while to relieve her pains and encourage sleep, she received carbonic oxide mineral water baths on alternate days with hot packs, the hydriatric treatment being successful.

After three weeks' treatment she passed out from under my observation, and has not been seen by me since.

Watkins, N. Y.

TRAINING FOR LAY WORKERS IN FUNCTIONAL RESTORATION.*

By Capt. E. A. Bott,

Toronto, Canada.

The object of this paper is not to present a comparison of curricula of special training courses inspired by the war, nor yet of established Departments of Physical Education. The object is rather to invite discussion of certain broad principles involved in preparing a body of workers who would be the manual laborers for the medical profession in physical therapy, both during and after the war.

During the war the whole community adjusted itself to be an efficient war machine. Many experiments, discoveries, and advances resulted not merely in the prosecution of warfare, but of production, governmental control, community cooperation, and particularly of medical and surgical practice, including physical methods of treatment. Now that the war has been brought to a successful conclusion, the obligation which the community has hitherto discharged to the military organization as a whole is reversed. What can the army hand back of its stewardship to the community? If the medical branch is to reciprocate this service, would it not involve immediate careful consideration of how to modulate and adjust its successful procedures, that they may be applied as intensively and widely as possible to meet analogous needs of the whole community? If it has been a national asset to develop special methods of treatment to hasten the convalescence of incapacitated soldiers, sailors, and aviators, is it less of a national asset, whatever difficulties may be involved, to extend the same high conception to the health and efficiency of all our incapacitated citizens? The return of our leading medical practitioners from war practice to civil life will not of necessity in itself achieve this end. Methods may be known, but unless the present spirit of preparedness and organization be perpetuated, their application will be all too local. No greater difficulty would confront such a program than that of providing a trained and competent personnel—professional and lay. For that reason I regard provision for training workers for functional restoration as an important phase of the general policy of education to be developed in the period of reconstruction.

The Military Problem.—Specialization: From a military standpoint the first question confronting a teaching program is the objective of the course, *i.e.* the degree of specialization for workers. Following the common practice of classifying post-surgical treatments into those which do and do not, respectively, demand cooperation and effort on the patient's part, we find on the passive side massage, electrical, thermo and hydro treatments, and on the active side different forms of applied exercise, *e.g.* muscle function training and general remedial gymnastics, also occupational therapy and curative shop work. Should lay workers be trained along all such lines, or only in one or in a selected group? (Occupational therapy and curative shops in Canada are under the direction of the Department of Soldiers' Civil Reestablishment, with a separate organization of instruction, and are therefore omitted from the following discussion of the relationship of courses in the Medical Corps.)

The arguments for general training of workers in several of the above lines are chiefly the following:

1. Economy of lay staff and treatment space, *i.e.* the equipment of all branches could be arranged in one or two rooms of liberal size and be used by all workers.
2. That fullness of knowledge contributes to efficiency.
3. That for psychological reasons as well as for proper sequence and proportion of treatment it is advantageous to have only one worker responsible for the treatment and progress of each patient.

The arguments for specialization are diametrically opposed to these, namely:

1. That the plea for economy in staff and space is based on the assumption of small treatment centers such as the Convalescent Home, whereas from the point of view of duplication in plant, equipment, administration, specialists, and all skilled help, the small establishment is uneconomical and inefficient, and consequently for military purposes only a small percentage of workers with general proficiency would be required.

*A paper presented at the International Conference on Rehabilitation of the Disabled, New York, March 18-21, 1917.

2. That as a general rule the efficiency of amateur workers in physiotherapy varies inversely as the number of branches of treatment they attempt to master, and that supervision cannot replace this want of skill.
3. That in military establishments of effective size, it is impracticable to consider a worker accompanying each patient to all his treatments, and that any loss in continuity due to specialization is more than counterbalanced by the added skill and thoroughness in each branch.

In different countries the policy in regard to the specialization of workers has differed, owing in part to local conditions and circumstances, and in part to differences in national psychology. Where there was a sudden and large demand for hospital accommodation early in the war this matter was of secondary importance, and consequently both amateur and expert workers were employed as existing agencies provided. In general, when training was improvised the policy of instruction was adjusted to suit the particular scheme of hospitalization adopted.

In Canada two facts were influential. In the first place for nearly two years of the war our men were treated chiefly overseas. Here conditions presented peculiar difficulties, and while the Canadian Army Medical Corps at the Ramsgate Special Hospital had the honor of initiating physical therapy in Britain along the lines previously developed by our French and Belgian allies on the Continent, pressure of work gave small opportunity for instruction of lay workers. The overseas policies of the Canadian Army Medical Corps later predominated at home, and in respect to lay staff, this is in part responsible for the degree of dependence we have placed on patient material as the source of personnel for operators. In the second place, in Canada prior to the war there was practically no supply of workers fully trained in physical therapy, nor any long established training school. Under these circumstances our policy of instruction has had to grow as we worked. Practical issues have led us to follow lines of intensive specialization, which policy the Director General Medical Services has endorsed. One form of specialization has been muscle function training, the operators therein being termed "trainers."

In terms of results achieved this specialization has proved successful, and from the instructor's standpoint it has been justified owing to the practical difficulty found in giving novices an adequate grounding in more than one technique in a short course of four or six months. It would not follow, however, that such specialization should be continued for workers who are to handle our pensioners and our civilian patients in the future.

Selection and Remuneration.—The selection and retention of workers for military needs present certain problems. Men and women have been proved successful as lay workers, particularly the latter, the chief sex difference being that men excel in collective treatment such as in the gymnasium and women in work requiring careful detail and patience, *i.e.* muscle function training. Otherwise the Canadian Army Medical Corps has employed male help exclusively only for hydrotherapy and for heavy massage. The male operators have been either patients or low category men selected for the most part by the Canadian Army Gymnastic Staff in Englind as remedial instructors, and drafted into other curative branches on the recommendation of medical officers familiar with their capacities. They are paid according to rank, usually as sergeants.

Women operators are certified members of the Women's Aid Department of the St. John's Ambulance Brigade, which uniform they wear with special insignia. They sign for one year's hospital service after training. With the exception of the muscle function trainers, women operators are paid $55.00 per month and a subsistence allowance amounting to $32.50 additional monthly. "Trainers," which were originally a local volunteer corps, have been retained in the Canadian Army Medical Corps on that status, receiving subsistence allowance. Unlike students in civilian life who are proceeding toward a profession, all our women operators have been paid during training, which necessitates a careful basis of selection and a rigorous probation system of two months' duration. Prospective trainers from different localities have been accepted on the direct personal recommendation of an officer of the C. A. M. C. or of the St. John's Ambulance Brigade, usually for capacity shown in other classes of volunteer war work. The wastage from probation in three classes of "trainers" has been less than 10 per cent. With the paid workers, however, secured through advertisement requiring only defined physical, educational, and medical qualifications, the wastage at probation has been about 20 per cent. The wastage in all women operators after graduation and before the expiration of contract has remained constant to date at less than 2 per cent. On the other hand, since the armistice the wastage of male operators, always heavier than of female, has more than doubled through requests for discharge, and threatens to affect the work very seriously.

With the approach of peace the situation in lay help is changing. The problem is how to procure and to maintain a proper supply and quality of workers sufficient to complete our war problem, and to undertake our civilian one. It is doubtful whether a monetary stimulus without adequate status, with all that that implies, will give a satisfactory solution.

Training.—Whatever degree of specialization be adopted in training for physical therapy, there exists a body of knowledge which is essential for all branches and may be given in common by synchronizing the classes. Our practice has been to give four such general lecture courses, *viz.*, anatomy (including osteology and myology) and physiology, taken concurrently and followed by a special course on joints and a clinical course on wounds concurrently. The remainder of the academic work and all the practice work (the latter receiving two-fifths of the total time) was taken in respective departments. For example, muscle-function training included educational gymnastics with special reference to the action of muscle groups, medical gymnastics (passive and resistive movements), kinesiology, theory and use of appliances, measure of disability (joint movement and muscle strength),

psychological factors in applied exercise, conferences, *x*-ray plates, bandaging, skin conditions, etc.

With our three classes of trainers during the past fifteen months we have experimented freely in methods of teaching. The following are points of procedure which experience has led us to put into effect in short intensive courses.

1. Morale of the class should be studied and cultivated. To announce the standards for rating proficiency at the beginning of the course, and make the class conscious of them throughout has been helpful. Equal credit is given for academic work, clinical practice, and general deportment.
2. Make haste slowly in instruction. Two study hours per day for amateur students, affording opportunity to organize their knowledge gives better results than a full program.
3. Lectures should be supplemented by group study—groups of eight supervised by a graduate student who gives daily "grinds" on lecture work.
4. Special teaching devices to visualize the subject matter economize time and effort.
5. The Socratic method is more effective for clinics than the demonstration method and should be supplemented by daily case conferences on practical work.
6. Special instruction is necessary on the psychological principles that underlie successful treatment in muscle function training—mentality of convalescence, psychological reactions between soldier patients and civilian women workers, progression in motives that stimulate self-help, etc.

The Civilian Situation.—Turning from the treatment of the soldier we are already confronted with the problem of expanding the therapeutic methods of physical reconstruction to the soldier-citizen and to the community at large. We are perhaps agreed that this program should evolve from the war program—but how?

There are significant differences between the military and civilian situations. In the first place, the clinical material will differ, particularly in the numerical proportion of different types of cases. Prevention as well as cure must be studied in the physical and likewise the mental impairment which civilian life produces, especially in relation to industry. Secondly, the civilian task will be complicated by the wide distribution of the clinical material, in general hospitals, in the home, in institutions, and in rural districts. Thirdly, the differences in psychological environment must be appreciated. Unlike the military patient, the civilian is a free agent, but with the corresponding responsibility of being on his own resources. He must seek treatment or at least consider it acceptable and worth while if offered to him. The motives which will make a successful policy of publicity and public education in this regard must be carefully studied.

The organization which would solve the problem of hastening civilian convalescence, whether it be by neurophysical clinics in large centers or in some other way, must be liberally conceived. In scope the plan should aim to provide for in-patients and out-patients as well as field workers and institutional aides. In motive the plan should not be urged merely on humane or philanthropic grounds, but rather on principles of practical economy of public health, with special emphasis upon the side of industrial hygiene.

The success of such a program will turn very largely on the question of personnel and training, and suitable provision therefor must be made in the curricula of suitable medical schools. As regards lay workers, I am satisfied that capable women in sufficient numbers would seek such openings. The service which patriotic motives have initiated will be perpetuated through the motives of community welfare and professional occupation. To this end, however, the status of workers must be carefully assured by adequate training of a general and thorough character.

Finally, if the various therapies now for the first time receiving wide recognition are to be expanded and wisely applied, they must be carefully sifted and tested by a program of research. In other words, if a scheme for community welfare is to be well balanced and effectively developed its advocates must urge that all three sides, the practical, the educational, and the scientific march forward together.

MEDICAL AND LEGAL ASPECTS OF THE AUTOMOBILE PLAGUE IN WASHINGTON.

By R. W. SHUFELDT, M.D.,

WASHINGTON, D. C.

Forty or more years ago, there was not a city in the United States that combined so many advantages and attractions as a place of residence, or offered more inducements to those in search of old-fashioned American homes, with all their comforts and surroundings, than did Washington. Everybody worth knowing seemed to know and to be on the most friendly terms with everybody else worth knowing, and society and the families were largely of the old stock, kind and charming in every way. Libraries, museums, and similar institutions were as good or even ahead of those of other cities, and amusements came along at a rate that left nothing to be desired on that score. All the country about was more than attractive, for it was young and fresh and still unmarred by man. Wild flowers flourished abundantly everywhere, while birds passed in thousands through the region with each vernal and autumnal migration. It was by no means a rare thing to observe in the elegant shade trees that lined the streets of old Washington such birds as the Baltimore oriole, scarlet tanager, blue grosbeck, and many others of a similar sort; while down on the Potomac, and in the marshes that lined the city along its southern limits, hundreds of marsh and water birds of many, many species were to be seen every year. At that time the sparrow of the Old World had not been introduced, and the boy's air-gun had not been invented.

The people who lived in Washington in those days will remember all this, and some of them will recall the Sunday afternoon promenades on what then existed of Connecticut Avenue—the elegant turnouts, blooded horses, and the mounts that lent so much to these afternoon occasions. As years came and passed, all this changed and changed radically;

old Washington was eliminated and with ever increasing rapidity. It changed in every conceivable feature as the population doubled and trebled, and the total made its impress upon the old order of things. Nearly all the wildness and the beauty of the surrounding country gradually passed, never to be restored. Nature died, and man's mockery usurped her place, and the grackles and sparrows ruled supreme in the city's shade trees and streets. Broad, smooth, manufactured roads led off for miles in all directions from those of the city's system; while the "betterments," as Natty Bumpo termed them, were responsible for the rest of the long list of transformations.

Then came the *automobile*—a curiosity at first, but gradually the successful rival of the horse wherever the latter existed, and finally, at the present time, practically the monopolizer of all the public roads and highways of the District of Columbia, with the congestion most marked within the city's limit. During the war, at a time when this congestion had arrived at its maximum, a condition existed throughout the entire city which, as one looks back upon it, is almost unbelievable. Every inch of parking-space was choked to the limit, and in most of the main thoroughfares traffic of every description was continually being brought to a standstill. An unbroken stream of cars passed up one side of most of the avenues, and a similar one down the other side. Where the road was more open, these machines paid no attention to the rules of speeding—the majority of them often traveling at a rate of from thirty to forty miles an hour. The Emergency Hospital and police records showed a death rate of slaughtered pedestrians, hit by automobiles, averaging one a day or even more, and minor injuries were too numerous to be mentioned. It is hardly necessary to say that the police—not numbering an army corps at any time—were practically helpless in the matter of abating either the killings or to arrest the hundreds of speeders. Thousands of the machines in the city belonged to transients or non-residents but this did not alter the conditions and for rather obvious reasons—probably rendered them all the more aggravated. Later, the congestion grew less, owing to the closing of our part in the war; to the return to their homes of the soldiery and their friends and relatives, and of the great army of war workers. Still, many hundreds did not thus depart, but arranged to make Washington their permanent abiding-place, and owing to this fact many thousands of automobiles remained in Washington.

In connection with this unprecedented invasion of automobiles, the city was very soon confronted with the problem of housing them,—that is, locating and building garages in sufficient number to accommodate the thousands that were licensed and carried on the books of the Chief of Police. Very soon it was discovered that the requirements could not be met, and as a consequence hundreds of cars were lined up along the curbs to the sidewalks throughout the city, or in groups in unoccupied city and suburban lots, and in other places. This was especially noticeable at night, though it was likewise the case for all hours of the day. Then came the garage-building craze. It was truly marvelous to note how they were squeezed into every nook and recess that would stand for one. Those who owned homes and aimed to have a garage for their automobile, cut in anywhere where the necessary space could be found. Some went into cellars, or the cellar and a part of the kitchen, and others sacrificed their little flower-gardens or the lawn. Then speculators commanded an entire alley, erecting cheap and hideous garages all the way down both sides of it. Hundreds of isolated ones were built in all sorts of places, even under the steps of handsome mansions, where no such disfigurement had ever been dreamed of before. Then came the *rent sharks*, who gobbled up the remaining recesses and nooks in which to erect garages that for architectural design would have disgraced a side alley in hell.

Then, in the huge army of drivers of all classes of these machines, from the ponderous army truck to the cheapest Ford, there grew up an utter disregard for each and all of the city ordinances that had been passed to protect the lives of pedestrians and others that crowded the city's thoroughfares. Very soon it was discovered that the Police Department could not control the situation, though, be it said to its credit, it handled the problem as best it could with the totally inadequate force at its command.

In a little while, exceeding the speed-limit was the order of the day; to kill some luckless pedestrian was a matter of daily occurrence, and served to help the local papers to the extent of a six-line news item. As this article was being written, the *Washington Post* gave a brief account of a metropolitan police officer who was shot through the lung by one of the occupants of a speeding car in his attempt to halt it; fortunately a simultaneous shot from his own revolver killed one of the three men in the runaway machine.

The fumes given off by these machines, night and day, have been announced by Doctor Woodward, of the city's Health Department, to be a menace to the health of those breathing them; and surely it is not difficult to imagine the effect of the various noises the machines give rise to, which, night and day, run the entire gamut from a bursting tire to the honking of the most unmelodious of all horns known to man.

So much, then, for all these various conditions as they exist at the present time; and it surely goes without the saying that they must have their effect and reaction upon the mental and physical constitutions of all those who are subjected to their influences. In the first place, the constant dodging of automobiles on the part of pedestrians, in order to avoid being either killed outright or maimed, exerts a most baneful effect, and is a subtle strain on the minds of nearly all nervous people, timid women, and those who suffer from certain diseases and disabilities. There are cases on record where the sudden shock from dodging a speeding automobile has caused instant death where marked heart disease was present in the person so affrighted.

Next we have the effects of the various noises, or the din when such noises emanate from several machines preforming in unison, and the added effects of the gasoline fumes upon those who are, for one unavoidable reason or another, subjected to these twin menaces to personal health and com-

fort. All this is bad enough during the day when many become more or less accustomed to it; but for not a few reasons it becomes an entirely different matter between the hours of ten P.M. and daylight. During the day, those most likely to be deleteriously affected are the ones of feeble minds and constitutions; victims of certain nervous diseases and psychoses; many workers in the various departments and branches of scientific and educational pursuits, and those engaged in experimental work of different kinds and degrees of delicacy.

As has just been stated, however, the most disastrous effects produced by the causes in question are to be observed in the case of any one susceptible to them in the great body of the city's population who keep regular hours with respect to retiring at night and arising in the morning. It would appear that no law has been passed governing the matter as to where garages may be built; and as the scramble to secure location has no parallel in history, the erection of these by no means sightly structures has taken place without the slightest regard for the health or comfort of any of the inhabitants. In no end of instances, miserable makeshifts of the sort referred to, accommodating from one to four automobiles each, have been built so close to other buildings and homes that there was no protection whatever either from the fumes of the gasoline or from the din created by the machine, when coming in or going out. Most people who follow the ordinary rules of health either sleep on a sleeping-porch or in a room with windows opened to their full extent. Now, there are hundreds of cases at this time in Washington where this most commendable practice has been entirely broken up through garages having, in any particular instance, been built either directly under the bedroom, or within twenty or thirty feet of a sleeping-porch. When a machine so housed returns, either during the middle of the night or in the early hours of the morning, the driver invariably brings his car to a standstill, allowing the motor to run, while he opens the doors of the garage. If more than one person are in the car, these disturbances may be accompanied by loud conversation, even with profanity, should there be any difficulty in getting the car housed, which is the case in a large percentage of instances. The escaping fumes of the gasoline rise and flow into the open windows of the bedroom above, or completely charge the air with their unhealthy stench over and around the sleepers on the porch, producing effects that vary in accordance with the mentality, constitution, or physical condition of those subjected to the ordeal.

Plenty of cases are now on record where people have not only been compelled to abandon their homes on this account, but to dispose of them at a loss in pocket. Where this step has not been feasible, and the menace and nuisance in no way abated, it has given rise to various physical and mental disorders in the healthy; rendered life intolerable to those suffering from any of the chronic troubles affecting the mind or body; disturbed the needed rest of thousands of infants and young children; produced the most harmful effects upon expectant mothers during the latter months of pregnancy, and in many instances ruined the tempers and militated against the success of the professional work of no end of other victims of this unchecked and calamitous condition of things. What all this gives rise to during the course of a year can perhaps be better appreciated by any physician residing in Washington, than by the non-professional resident of the city.

Not a few of these garages have been erected in lots in the rear of homes solely for the purpose of renting them to others. So hastily has this been done in some instances, and so keen the greed of the builder, that no precaution whatever has been taken with respect to the safety of the structure. Should one desire proof of this, one need go no further than to the records of the Commissioner of Buildings of the District, where due search will furnish one with a case of the caving-in of the roof of a half-built, cheaply constructed brick and mortar garage, that came near killing one of the workmen engaged upon it at the time. This matter is simply referred to in the present connection as furnishing another class of cases where physical injury or suffering has been caused by the automobile epidemic in Washington—an epidemic that, at this writing, rages with ever-increasing intensity, and presents no hope of abatement to which the hundreds of victims may look for relief.

Well may the question now be asked, have we available any remedies to meet this state of affairs, and, by adopting them, to protect the lives and comfort of the city's residents? Surely there should be means which, if adopted and enforced, would bring the necessary relief. Where one's health has been impaired—either temporarily or permanently—it is clear that an action at law may be instituted, which, if won by the plaintiff, may rectify matters in one way or another. The offending party or parties have been cautioned by the police to keep more reasonable hours, with respect to entering and leaving the garage, controlling the gas fumes, noise, and so on; and where the offenders have been ladies or gentlemen, this has usually resulted in their promptly changing their garage quarters and renting elsewhere; but where the reverse obtains, however, it usually has the effect of making all the objectionable conditions worse, developing, *pari passu*, the unrefinement and the brutal nature of the offender. Thereupon one will be advised by the police to take the matter into the police court for remedy, which simply means loss of time and money, and, through the influence of the city's automobile clique, have the case promptly decided against the complainant.

What is really needed in order to protect the community against this serious, ever-increasing, and dangerous menace is to have certain city ordinances passed at once, enforcing the same with the utmost strictness and celerity. Obviously, these remedial laws should simply meet the conditions; then, it goes without the saying, all this undesirable not to say dangerous state of affairs would be rectified. Occupants who have their automobiles of any description so near the sleeping apartment or sleeping-porches of private residences, that the noise and gas fumes they give rise to when taken in or out happens to prove either a menace or an annoyance to the occupants of such, should be prevented by law from taking their cars in or out of the garage between the hours of 10 P.M. and 7 A.M. This ar-

rangement should rest entirely upon the lodgment of complaint; for if the latter be not filed and the law in force, it is clear no harm or inconvenience obtains, and the user of the garage need not heed the law until such objection is made. Should protest be filed in any case, however, and no regard to it be paid on the part of the offender, it should be considered a misdemeanor and dealt with accordingly by the courts.

3356 Eighteenth Street, N. W.

A STUDY IN REHABILITATION OF THE DISABLED SOLDIER.*

By JOHN CULBERT FARIES, Ph.D.,

NEW YORK.

CHIEF, DEPARTMENT OF VOCATIONAL COUNSEL, RED CROSS INSTITUTE FOR CRIPPLED AND DISABLED MEN.

It is fortunate that the first American book dealing with the problem of the disabled soldier should be the labor of love of a man who knows the subject he treats of and can write clear, vigorous English. His familiarity with the problem of the handicapped antedated the war by several years, and the relations he established in antebellum days with those interested in the subject have brought to his hand an invaluable mass of material that cannot be duplicated in any other collection. Familiarity with the subject has made it possible for him to evaluate all efforts for the rehabilitation of the disabled and penetrate to the principles involved. He does not theorize upon the principles, but no reader can finish a perusal of the book without a very clear idea of the basis upon which the future development of this latest constructive social effort must rest.

It is one thing to know a subject and another to put it across so that the average reader may congratulate himself that he can walk new paths with a firm tread. To do this a writer must be able to handle the English language effectively. And this is precisely what Mr. McMurtrie does without circumlocution, redundancy, or obfuscation. His sentences are terse and vigorous. His meaning is perfectly obvious without rereading and the fatigue often experienced when being initiated into a new subject is entirely lacking. The book is not intended to be so much a treatise on the disabled soldier as a plain recital of facts in which the principles are implicit. The facts recorded are selected with discriminating judgment and reflect the best thought and effort in the chosen field.

The disabled soldier is a man who has suffered some impairment of his human mechanism through the vicissitudes of war. Other men have experienced similar limitations through disease and industrial accidents. The attitude of society in the past to the cripple forms a dark background in the opening chapter. The evolution through the centuries of effort to ameliorate the condition of the unfortunate shows a growing appreciation of the value of the individual. Primitive social groups eliminated the man unfit to fight or produce. Modern society strives to restore him to productive activity by developing the remaining powers and nurturing latent capabilities. The contrast between the first and last chapters is an illuminating comment upon the influence upon society of Him who taught men not to "break the bruised reed or quench the smoking tow."

The disabled soldier is a man who was a productive unit before his injury and who, in all fairness to himself and his country, must be returned to the ranks of the productive. So is the disabled civilian. But definite steps to this end were but haltingly taken before the Great War thrust upon the world its unescapable duty. The beginnings of effort to rehabilitate the disabled civilian are shown to have been made in martyred Belgium in the direct line of the invading Hun. The seeds of that work were propagated in war-torn France and quickly spread to other belligerent countries.

Facing a problem of ever-growing proportions, society has been led to put a new valuation upon the splendid achievements of men who through sheer force of character, and without the aid now being offered to the handicapped, have surmounted physical obstacles. A new interest has been awakened in the successful cripple and what he has accomplished has been storied and filmed for the encouragement of the victims of war. The heroism of abridged men has stirred the disabled soldier to a new heroism in the dull, gray days after "the tumult and the shouting dies." Many of these men are now "doing their bit" denied them in recruiting days.

Every new work must develop a technique. Appropriate means must be devised to bring about the desired end—the industrial rehabilitation of the disabled man. The methods employed to restore men to functional activity and industrial efficiency are clearly outlined by the writer. A complete view of the needs of the man from the moment of his injury to his final restoration is given the reader. The work is seen to be psychical as well as physical, moral as well as vocational, social as well as individual. The environment of the man is a matter of solicitude as well as his treatment and education.

Touching upon the question of pensions, the author takes a bold stand: "Granted a constructive and effective program for the reconstruction of the disabled soldier and sailor, a low pension scale may be a blessing in disguise, in that it may force the men to make plans for support through their own efforts." He sees the greatest need of the disabled soldier to be "not industrial school equipment, not elaborate courses, not splendid buildings—but the finest men the country affords to help him in the critical period immediately following disablement. Where there is found exceptionally successful work with the injured soldiers, there will be found a man of unusual qualifications."

In starting a course for the disabled man two angles must be determined if shipwreck is to be avoided. First, the capabilities of the man must be assessed in the light of his physical limitations. Second, an adequate wage must be kept in view. Training, as such, must be subordinated to his economic necessities. In other words, the job selected for the individual must be one in which his particular disability imposes the least handicap and which promises him steady employment at adequate wages. The discovery of such a job requires a survey of the whole field of industry from the viewpoint of the man with definite physical limitations. Here is

*"The Disabled Soldier," by Douglas C. McMurtrie. New York: The Macmillan Company, 1919.

a new field of effort for the industrial expert who must approach his work with a new interest—that of finding a job for the man with abridged powers. The author reviews the various occupations and industrial processes that have been found suitable for disabled men in different countries. In the light of these industrial surveys "the courses of training must be intensive and practical rather than theoretical. Every feature of instruction must be evaluated according to whether it affords direct assistance to the man's earning a living." The reaction of various technical schools and industrial establishments to the exigencies of the situation is considered in detail.

The wages to be paid handicapped men raises a perplexing question. How to steer between the Scylla of the exploitation by employers of men fortified by a pension and the Charybdis of the maintenance of a minimum wage by organized labor requires the united wisdom of both employers and work people. Wage advisory boards have been found valuable in adjusting the differences that are bound to arise.

The settlement by the government upon the land of disabled soldiers whose life in the open has tempted them to seek an agricultural life has received the serious attention of France, England, Canada, Australia, New Zealand, Germany, and the United States. Another opportunity which government may open to their ex-service men is in the line of civil service appointments. That there are dangers, both to the morale of the disabled man and to the efficiency of public service through the influence of baneful political patronage, is clearly recognized. The danger of leaving trained men to the discouragement of new occupations without adequate after care and oversight is pointed out. An adequate program for the rehabilitation of the disabled must include follow-up work which shall insure the establishment of the worker in his new job.

The education of the public to its duty to the disabled man is a very considerable part of the work. The family must be taught to encourage the injured man to self-help rather than to a dependent attitude. The employer must be taught to give the disabled man a job, not for charity's sake, but upon the basis of utilizing labor that would otherwise be unproductive. This means the employment of handicapped men in all those processes in which he can be as efficient a worker as a normal man. Only upon this basis can a proper relation be established between the employer and the worker, a basis which maintains the self-respect of each. The public must be taught that such an attitude toward the discharged soldier as tends to confirm him in his feeling of dependence upon public bounty only degrades him to the level of mendicancy. Lionization may create helpless cubs if wrongly directed. An ounce of wise assistance is worth pounds of degrading pity.

Various types of disability are discussed in successive chapters dealing with those who have suffered amputations, the blinded, the deaf, the tuberculous, and the neurasthenic, and the net results of efforts in their behalf are indicated.

An historical review of the national programs for the rehabilitation of the war-disabled discloses the wealth of material gathered through the research work directed by Mr. McMurtrie. The facts are selected with admirable discrimination, and the net result is a complete picture of the attempts of the belligerent nations to repair the human waste and damage of war. The efforts on both sides the Hindenburg line are impartially surveyed, and the amazing thing is that so complete a picture of the efforts of the Teutonic allies has been possible during the progress of hostilities and the interruption of communication. The neutrality of Switzerland and the genius of the author for stimulating the collection of data are contributing factors.

The book closes with a brief outline of the program of the United States which is as generous as its unbounded resources. This nation has the decided advantages of the experience of those earlier in the war. The results should be commensurately great. The complete success of the work rests, as is fit in a great democracy, with the people of the United States.

SOME OF THE SALIENT DUTIES OF A NURSE.*

By S. E. EARP, M.D.,

INDIANAPOLIS, IND.

THE nurse does not occupy the position of a czar or high executioner, nor that of a slave; like the doctor she is a happy medium. She is clothed with authority, but when such is exerted beyond the field of duty belonging to a nurse it furnishes the groundwork for criticism and is the nucleus of discontent.

Sulkiness is not in the vocabulary of the nurse—she is in school to be taught and in the home to be active in response to the needs of the patient, with a courtesy which should be characteristic of a gentle disposition.

Cleanliness, neatness, and good manners are necessary attributes.

Loyalty to doctor, associate nurses, alumni, and the graduation school is part of the stock in trade of a nurse and is an investment that continuously bears interest. A nurse is not necessarily licensed to admire a doctor, but if she has suggestions or comments to make, he is the one to go to, not others, and especially not the patient. Criticism of a doctor with whom there has been an association during sickness, whether it be in or out of the sickroom, on or off duty, is always unwise, and places the critic in the rôle of a "backbiter" and will never fail to bring a fulfilment of the old adage, "chickens always come home to roost." There may be evidence of a grouch in members of a family, the patient, and possibly the doctor, but diplomacy is a good remedy, and gentleness of disposition and accuracy in the performance of duty by the nurse will do wonders in clearing the atmosphere.

During the training and afterwards, if there are points that are imperfectly understood, do not slothfully wait for opportunity to bring enlightenment, but seek the library as your best friend and instructor.

Study the patient's condition minutely so that

*Abstract of a lecture before the Training School for Nurses of the Indianapolis City Hospital, reported by Vivian Masters, R.N.

a conference with the doctor will bring good results to all concerned.

It is well that the patient has the confidence of the nurse and the nurse the confidence of the patient, but the nurse should not be the confidant of the patient. Such a condition of affairs quite frequently has brought about woeful results, and the "don't" might be the text for a good sermon.

All legitimate desires of a patient should be gratified promptly, and in conversation the nurse should always face the patient. Experience shows that the suggestions of a patient are not always trivial and have very often proved valuable to both nurse and doctor.

Patients should never be discouraged and never left in suspense. If a remedial measure will be attended by some risk, and danger is contemplated, candid information given gently and with a kindliness of spirit will bring relief and prepare the patient for the ordeal, if such it be.

To keep a patient waiting for a urinal or bedpan is cruelty.

During the presence of visitors there should be no fatigue of the patient; if noticed, put a quietus on it, and save untoward consequences later on. Allow no home worries to be discussed.

Deception, even when there is a mental defect, is likely to be recognized and is often a dangerous procedure.

The character of food is outlined by the doctor, and yet by the nurse it can be made inviting. Sometimes a patient who has either an acute or chronic mental defect will keep food in the mouth unconsciously for a long period of time, or perhaps take several other morsels additionally and so run the danger of the food entering the lungs. Always be sure that food taken into the mouth has been swallowed.

During paracentesis abdominis I have observed instances wherein the nurse had almost full supervision. In such a case the nurse should see that the bladder has been catheterized before the operation and all of the fluid should not be withdrawn during one sitting, lest there be collapse. This should be borne in mind when there is need of catheterization of a greatly distended bladder; and the same caution is to be observed in the case of removal of fluid from the chest. The position of the patient before and after operation is also an item of importance.

In a few words let us consider the question of ethics an all-important one. In brief, if physicians as well as nurses would let the Golden Rule be their guide, neither would go far wrong. Reflect upon it, study it carefully, and you will recognize its great value.

631 Occidental Building.

Grippe in Brazil.—October was the month in which Brazil was principally victimized by the pandemic. A report given out by the National Academy of Medicine is pessimistic concerning our knowledge of the rapid dissemination and mode of transmission of the disease and our relative impotence in prophylaxis, both from our ignorance of causes and the lack of practical enforcement measures on the part of the centralized power, there being no jurisdiction over half of the population.—*Brazil-Medico.*

Medical and Surgical Lessons of the War.

WAR ACTIVITIES OF THE UNITED STATES PUBLIC HEALTH SERVICE.

By BENJAMIN S. WARREN, M.D.,
ASSISTANT SURGEON GENERAL, U. S. P. H. S.,
AND
CHARLES F. BOLDUAN, M.D.,
CHIEF, SECTION OF PUBLIC HEALTH EDUCATION, U. S. P. H. S.

IN describing the activities of the United States Public Health Service, so far as they were directly related to the prosecution of the war, it may be well to record that though many of these activities were not undertaken until 1918, developing as they did out of necessities arising as the war progressed, the need for most of them was foreseen by the Service, and was made the subject of official recommendations. Thus, in a report dated February 4, 1917, two months before the entry of the United States into war, a board of officers of the United States Public Health Service formulated a program of activities which could be undertaken by the Service in order to assist in the prosecution of the war. Among these are mentioned:

> The sanitation of ports and places within the United States in order to prepare them for camps of mobilization, concentration, or training for the Army or Navy.
>
> The sanitary supervision of mobilized industrial forces.
>
> Medical and surgical relief to sick, wounded, or disabled soldiers and sailors at relief stations of the Service.
>
> Medical and surgical relief to mobilized industrial workers.
>
> Laboratory operations, including both research and manufacture of serums and vaccines.

This was supplemented by a memorandum, dated April 7, 1917, outlining desirable activities of the United States Public Health Service in the field of industrial hygiene, especially as related to war industries.

It was clear that the carrying out of the contemplated war activities demanded a considerable increase in the personnel of the Public Health Service. In order that such an enlargement of the personnel might subsequently be available for other public health emergencies Congress was asked to authorize the establishment of a Reserve in the Public Health Service, to consist of medical officers, sanitarians, engineers, and other qualified experts.

A bill covering this matter was introduced into Congress and passed by the Senate on June 18, 1917, but was not adopted by the House of Representatives until more than a year later. The Reserve Act became a law on October 27, 1918.

However, without waiting for authority to establish a Reserve, the pressing demands made upon the Public Health Service led to a great increase in the personnel of the Service. Thus at the close of the fiscal year, June 30, 1917, the Service consisted of 538 professional personnel, 1,506 other personnel, a total of 2,044; at the close of the fiscal year, June 30, 1918, the professional personnel amounted to 1,472, and the other personnel to 3,515, a total of

4,987. These figures do not include the personnel of the American Red Cross, State and local health authorities operating under the direction of the Service.

In the early part of 1918 it became evident that a number of different Government agencies were undertaking what were really Federal public health functions. It was realized that unless some plan of effective coordination was devised, there would be much duplication and waste of effort in this important field.

Under these circumstances, very soon after the passage of the Overman Act, the Public Health Service initiated action looking toward bringing all Federal civil health functions under the supervision and control of the Public Health Service. An executive order effecting this was signed by the President on July 1, 1918. The text of this was as follows:

Whereas, In order to avoid confusion in policies, duplication of effort, and to bring about more effective results, unity of control in the administration of the public health activities of the Federal Government is obviously essential, and has been so recognized by Acts of Congress creating in the Treasury Department a Public Health Service, and specially authorizing such Service "to study the diseases of man and the conditions influencing the propagation and spread thereof" and "to cooperate with and aid state and municipal boards of health;"

Now, therefore, I, Woodrow Wilson, President of the United States, by virtue of the authority vested in me as Chief Executive, and by the Act "authorizing the President to coordinate or consolidate executive bureaus, agencies and offices, and for other purposes, in the interest of economy and the more efficient concentration of the Government," approved May 20, 1918, do hereby order that all sanitary or public health activities carried on by any executive bureau, agency, or office, especially created for or concerned in the prosecution of the existing war, shall be exercised under the supervision and control of the Secretary of the Treasury.

This order shall not be construed as affecting the jurisdiction exercised under authority of existing law by the Surgeon General of the Army, the Surgeon General of the Navy, and the Provost Marshal General in the performance of health functions which are military in character as distinguished from civil public health duties, or as prohibiting investigations by the Bureau of Labor Statistics of vocational diseases, shop sanitation, and hygiene.

(Signed) Woodrow Wilson.

The White House, July 1, 1918.

Before taking up the war activities of the Public Health Service in more detail it may be well to point out that much of the work of the Service in dealing with the pandemic of influenza in the fall of 1918 was imposed on the Service because of the entry of more than 30,000 physicians practising in the United States into military service. With the spread of the pandemic over the United States urgent calls were addressed by stricken communities to the Public Health Service for medical assistance. In response to this the Public Health Service organized a mobile corps of nearly 1,100 physicians and detailed these to render the needed medical attention. The emergency expenditures required for this and other purposes in dealing with the pandemic were met by a special appropriation of $1,000,000 voted by Congress on October 1, 1918.

In describing the war activities of the United States Public Health Service it may be well to consider these under the following heads:

Sanitation of Extra-cantonment Areas.
Industrial Hygiene.
Scientific Research.
Production and Supervision of Biological Products.
Campaign against Venereal Diseases.
Medical and Surgical Relief.
Miscellaneous Activities.
Publications of the Service.

SANITATION OF EXTRA-CANTONMENT AREAS.

Inauguration and Organization of the Work.—With the outbreak of the war it began to be realized that the backward state of public health administration throughout a large part of the United States threatened to constitute a distinct handicap to the country's military effectiveness. It was felt that this handicap could be materially reduced only by an intensive system of federal health supervision in and about zones surrounding military camps and important industrial centers engaged in war work (mines, munition plants, shipyards). Within the camps themselves responsibility for the supervision and control of sanitary matters rested with the Army Medical Corps; their jurisdiction, however, ended with the camp boundaries and the Public Health Service was responsible for the correction of insanitary conditions which menaced them from without.

In the summer of 1917, in cooperation with the army authorities and State and local health officers, the Public Health Service undertook to sanitate a zone around each of the 26 military cantonments; the end of 1918 saw 47 zones, most of them around military cantonments, under the operation of the Public Health Service. In most instances the officer of the Service who was in charge of a zone was appointed by the State and local health authorities a deputy health officer. Inasmuch as the intensive health work was carried on primarily for the protection of the military forces and of industrial workers engaged in essential war work, it was manifestly unjust to ask the local communities to bear the entire expense involved. In the circumstances most of the work was done with Public Health Service sharing the expenses. Moreover, as will be described in a moment, the American Red Cross maintained a number of sanitary units which rendered invaluable aid in the sanitation of these areas.

At the same time it was felt that the intensive health work carried on as a war measure should be made to constitute really a demonstration of profitable health activities and that every effort should be made to have the local and State health authorities continue the work after the war emergency had passed. To this end it was the aim to rouse a wider interest in health matters, to present the cost and the results of health work in the form of simple statements published in the local newspapers, to invite public attention to attainable results as shown by the experience of other communities—in short to seek in every way to make the people realize that "public health is purchasable."

American Red Cross.—It is certain that the work of the Public Health Service, especially as it related to the sanitation of extra-cantonment and industrial areas, was greatly facilitated by the effective aid rendered by the American Red Cross. At the re-

quest of the Surgeon General the War Council appropriated funds, and authorized sanitary units to be operated in such areas under the direction of officers of the Public Health Service. The first of these units was organized at Columbia, S. C., and by the end of the following year, January 1, 1919, 36 such units were in operation.

A Red Cross sanitary unit consisted of one or two bacteriologists, a chief sanitary inspector and a number of sanitary inspectors, a supervising public health nurse with the required number of assistants, clerks, stenographers, and laboratory assistants, and miscellaneous employees such as laborers, messengers, etc.

In addition to the salaries of these employees the Red Cross paid their traveling expenses, including, where necessary, the service of automobiles, and it also provided limited funds for sanitary necessities of the poor. The direction of the work of the sanitary unit was always lodged in an officer of the Public Health Service. Moreover, a general supervision over the work of the various Red Cross units was exercised by a senior officer of the United States Public Health Service, detailed to Red Cross headquarters as liaison officer.

Cooperation of State and Local Health Authorities.—Without the cooperation on the part of the State and local health authorities it would have been impossible to carry on the intensive health activities dealing with the sanitation of extra-cantonment areas. In many instances this work was supported by funds supplied by State and local authorities. Such support was often invaluable because of the legal limitations on the character of expenditures by the Federal health authorities. In addition to this, officers of the Public Health Service detailed to extra-cantonment areas were usually given appointment as deputy health officers by the State and local authorities, thus arming them with the necessary authority to administer health regulations. It was often discovered that regulations were lacking to provide the desired control. In these cases model regulations prepared by the Public Health Service were recommended, and were usually adopted by the proper local authorities.

Activities Carried On.—The work done in the sanitation of the areas already mentioned has been of endless variety: In some rural areas it has consisted largely of measures designed to control the spread of malaria, in others of efforts to provide proper disposal of human excreta, to protect drinking water, and to safeguard the milk supply; in urban communities, the home of important war industries, questions of sanitary housing, of the control of communicable diseases, of industrial hygiene demanded a large share of attention.

Some idea of the magnitude of this undertaking can be gained from the following list of places where this intensive health supervision was maintained:

EXTRA-CANTONMENT ZONES.

Following is a list of the extra-cantonment areas where the Public Health Service carried on intensive health supervision, and where Red Cross sanitary units were operated:

Alexandria, La.	Sanitary Unit No. 22
Alexandria, Va.	Sanitary Unit No. 31
Americus, Ga.	Ex. Cantonment Zone only
American Lake, Washington.	Sanitary Unit No. 18
Anniston, Ala.	Sanitary Unit No. 8
Atlanta, Ga.	Sanitary Unit No. 11
Augusta, Ga.	Sanitary Unit No. 25
Ayer, Mass.	Sanitary Unit No. 10
Brunswick, Ga.	Ex. Cantonment Zone only
Charleston, S. C.	Sanitary Unit No. 33
Charlotte, N. C.	Sanitary Unit No. 20
Chattanooga, Tenn.	Sanitary Unit No. 16
Chillicothe, Ohio	Sanitary Unit No. 12
Columbia, S. C.	Sanitary Unit No. 1
Columbus, Ga.	Ex. Cantonment Zone only
Des Moines, Iowa	Sanitary Unit No. 4
El Paso, Texas	Sanitary Unit No. 24
Fayetteville, N. C.	Sanitary Unit No. 35
Florence, Ala.	Ex. Cantonment Zone only
Fort Worth, Texas	Sanitary Unit No. 23
Gulfport, Miss.	Ex. Cantonment Zone only
Greenville, S. C.	Sanitary Unit No. 13
Hattiesburg, Miss.	Sanitary Unit No. 6
Houston, Texas	Sanitary Unit No. 27
Jacksonville, Fla.	Sanitary Unit No. 29
Lawton, Okla.	Sanitary Unit No. 34
Leavenworth, Kan.	Sanitary Unit No. 5
Lake Charles, La.	Ex. Cantonment Zone only
Louisville, Ky.	Sanitary Unit No. 3
Little Rock, Ark.	Sanitary Unit No. 2
Millington, Tenn.	Ex. Cantonment Zone only
Macon, Ga.	Sanitary Unit No. 14
Manhattan, Kan.	Sanitary Unit No. 15
Montgomery, Ala.	Sanitary Unit No. 19
New London, Conn.	Sanitary Unit No. 32
Newport News, Va.	Sanitary Unit No. 9
Petersburg, Va.	Sanitary Unit No. 7
Portsmouth, Va.	Sanitary Unit No. 28

The organization built up to deal with the sanitation of extra-cantonment areas dovetailed into the existing local health machinery, thus making up a complete sanitary unit. The amount and character of the work done by the United States Public Health Service therefore varied, in the different areas, according to the amount and character of the work which State, city, county or other local health authorities were willing and able to do. Altogether the end of the year 1918 found 49 commissioned medical officers and 72 acting assistant surgeons engaged in this work by the United States Public Health Service. These, with sanitary engineers, scientific assistants, epidemiologists, sanitary inspectors, and public health nurses, made up a total force of over 500 exclusive of laborers.

Following is a more detailed description of the activities carried on to sanitate these special areas:

Malaria Control.—In general it has been the aim of the Public Health Service to establish around each cantonment a mile-wide belt entirely free from mosquito breeding places. The means to attain this has varied with the local conditions. In some instances extensive swamp areas have been ditched and drained, in others sluggish water courses have been channeled and straightened, here small ponds have been drained dry, there, they have been filled in; in still other cases they have been oiled. Now and then it was feasible to poison mosquito breeding waters by turning into them industrial wastes.

Altogether the total area in and about camps and

war-industrial communities which was thus treated to prevent the breeding of mosquitos was over 1,200 square miles. The total cost of the work was $1,300,000, of which approximately 35 per cent. was obtained locally. Nearly 2,500 miles of ditches were dug and the population protected by these measures was 1,730,000 civilian population and an average of 826,000 military population.

Illustrative of the operations carried on it may be mentioned that at Park Field, near Memphis, about half of the work consisted in regrading and clearing natural water courses. The total area involved was sixteen square miles, and the total cost was $65,000.

In other areas, especially where the soil was free from roots, the antimosquito work consisted largely of cutting V-shaped ditches with a horse plow. Such ditches were from 18 to 25 inches deep and about 2½ to 3 feet in width at the top. Much of the work at Montgomery, Ala., was of this type. There approximately 86 square miles were protected at a cost of $45,000, involving the cutting of 123 linear miles of light ditches.

In still other areas it was necessary to cut and clean an outlet to a swamp and to secure good drainage of such camps when water levels were favorable. This often involved heavy operations, even including blasting with dynamite. The costs have varied considerably, depending on local conditions. Operations of this kind were carried on at Macon, Ga. They protected an area of 26 square miles, involved the cutting of 50 linear miles of ditches, and cost $107,000. Similar work was carried on at Hattiesburg, Miss.

General Sanitation.—Under this head are embraced a number of health activities having to do largely with the correction of the insanitary environment of the rural population usually in a zone from 1 to 5 miles wide around the military cantonments. Much of the work consisted in the improvement of local water supplies and in provision for the safe disposal of human excreta. In connection with the latter, in some communities the double-compartment concrete vault type of privy was largely introduced; in others, sanitary pails combined with scavenger system were utilized. In all cases attention was given to preventing the spread of diseases of excretal origin by flies.

Vaccination.—In order to reduce to a minimum the prevalence of smallpox and typhoid fever in the extra-cantonment areas much emphasis was placed on protective vaccination. Smallpox and typhoid vaccines prepared by the Hygienic Laboratory were administered by officers of the Public Health Service. The extent of this activity is indicated by the following figures showing total vaccinations in the extra-cantonment areas:

Antityphoid inoculations 259,888
Smallpox vaccination 107,497

Morbidity Reports.—With the inauguration of the intensive health work in the extra-cantonment areas, the possibility was presented of securing more complete morbidity reports than had previously been received from any miscellaneous group of the population. Arrangements were accordingly made to secure the following regular reports:

1. Daily morbidity reports, mailed to the Public Health Service.
2. Weekly telegraphic reports, for publication in "Public Health Reports."
3. Records of individual cases of illness, showing diagnosis, age, sex, color, occupation, date of onset, and termination of the disease.

One of the important outcomes of the collection of these morbidity reports was the possibility of currently transmitting the information thus obtained to the medical authorities of the Army and Navy and the Council of National Defense. Accordingly, daily statements were prepared for this purpose containing the following:

1. Transcripts of monthly reports from collaborating epidemiologists and state health officers. (This information was thus available to the military authorities prior to publication in "Public Health Reports.")
2. Transcripts of the daily health reports from the extra-cantonment areas.
3. Transcripts of weekly post card morbidity reports from the larger cities.
4. Information of unusual or immediate importance relative to the prevalence of disease.

Health Education.—Much of the work in the extra-cantonment areas was necessarily educational, and was carried on largely by personal visits to the individual homes by public health nurses or sanitary inspectors. At these visits attention was called to matters relating to child hygiene, to the importance of cleanliness and the proper disposal of human excreta, the need of pure water and milk supplies, the rôle of flies in the transmission of disease, the recognition and prevention of communicable diseases, the control of mosquito breeding, and any other matters of special importance to the particular home visited.

Typhoid Fever Index.—Among the different statistical indices in use by sanitarians for measuring the results of public health activities, the prevalence of typhoid fever has generally been accepted as simple, useful, and reliable. Omitting those extra-cantonment areas which were not established until after the beginning of 1918, the carefully collected morbidity reports from these areas show a total of 2,835 cases of typhoid fever, in 31 areas having a total population of at least 3,033,000. This is equivalent to a morbidity rate of 93.5 per 100,000 population and an estimated mortality rate, according to the usual method of calculation, of 9.35 per 100,000 population.

This rate may fairly be compared to the typhoid fever rate of the United States Registration area, which was 13.3 in 1916 (the latest figures available). As a matter of fact the results achieved were even more favorable, for inasmuch as most of these extra-cantonment areas were located in the South, the comparison should really be made with the typhoid rate of that part of the country. Such a comparison has been made in the following tabulations:

Typhoid Death Rates Per 100,000.

Texas (1917)	19.2	Extra-cantonment areas (1918)	11.0
Georgia (1916)	22.0	Extra-cantonment areas (1918)	7.6
Virginia (1916)	25.1	Extra-cantonment areas (1918)	9.8
S. Carolina (1916)	34.1	Extra-cantonment areas (1918)	7.2
Alabama (1917)	38.0	Extra-cantonment areas (1918)	15.1

Altogether the conclusion is warranted that the public health activities carried on in the extra-cantonment areas resulted in a marked improvement in sanitary conditions and a consequent high degree of health protection not only to the people living in these areas but to those in the military and industrial camps there located.

Malaria Index.—It may be mentioned that malaria, which was a serious potential disability factor about many of the camps, especially those located in the South, was practically eliminated from the soldier population and only 3,160 cases were reported to the Public Health Service during the malarial season of 1918 from among the civil population of three and three-quarter million, a rate of 83 per 100,000. From such data as are obtainable from previous years this was a tremendous reduction in the malarial rate in these communities. These results may well be compared with those in Panama, especially since they were obtained, not under military conditions but through the voluntary work of a civil population.

INDUSTRIAL HYGIENE.

An important contribution to promoting efficiency in war industries consisted in the health and sanitary supervision of these industries by the Public Health Service.

In cooperation with the Safety and Sanitation Division of the Industrial Service Section of the Ordnance Department, officers of the Public Health Service conducted examinations as to the hygienic conditions of the explosives industry in such plants as—

The Etna Explosive Company, Mt. Union, Pa., and Emporium, Pa.
The Atlas Powder Company, Webster, Pa., and Perry Point, Perryville, Md.
McArthur Brothers' Bag Loading Company, Woodbury, N. J.
Nitrate Plant No. 2, Muscle Shoals, Ala.
Penn Trojan Powder Company and Chemical Company, Allentown, Pa.
Picric Acid Plant, Brunswick, Va.
Quaker Valley Works of John B. Semple Company, Sewickley, Pa.
Roessler & Hasslacher Chemical Company, Perth Amboy, N. J.
Tullytown Bag Loading Co., Niagara Falls, N. Y.
U. S. Explosives Plant, No. 6, Nitro, W. Va.
U. S. Nitrate Plant, Toledo, Ohio.
Western Cartridge Co., West Alton, Ill.

Particular attention was paid to the subjects of TNT poisoning and poisoning from other comparatively new similar chemicals and explosive compounds. Laboratory work incident thereto was done by the Hygienic Laboratory and the National Research Council.

The Public Health Service also conducted investigations of the sanitary condition of a number of large aniline and other chemical factories; the electro-chemical industry of Niagara Falls, as well as the storage battery and abrasive industries.

Surveys were also made of health conditions of establishments manufacturing uniforms and other articles of clothing equipment for the United States Army, mostly in the State of Ohio.

The Demonstration at Nitro, W. Va.—On the theory that the Government should take the lead in demonstrating how to safeguard the health of industrial workers, arrangements were made at the request of the Secretary of War to have the United States Public Health Service undertake the sanitation and medical and surgical relief at the United States Explosives Plant located at Nitro, W. Va. Some idea of the magnitude of the work thus undertaken by the Public Health Service may be gained from the fact that it required the services of 35 medical officers, 80 nurses, and numerous other persons including laborers, artisans and clerks. The total personnel was about 500, not including laborers in the Sanitary Department, who numbered approximately 300.

Inasmuch as the sanitary and medical work began with the construction of the plant, the work at first had to do largely with the health supervision of the large army of temporary employees engaged in construction work; subsequently as this phase of activity subsided, matters of industrial hygiene arising with the operation of the plant required an increasing amount of attention. A brief summary of the more important phases of this work may be of interest.

Examination of Applicants for Employment.—A suitable building was erected and properly fitted out, both in supplies, equipment and personnel, for the purpose of examining physically all applicants for employment. In this way it was possible to control the introduction of dangerous communicable diseases and to reject for employment those disqualified by disease or physical defects. Out of the 45,858 applicants examined to July 1, 1918, only 0.8 per cent. were permanently rejected for employment. In addition to this 1.8 per cent. were rejected temporarily. Most of the latter were cases of venereal disease, and the infected individuals were referred immediately to the proper department for treatment. In most cases as soon as they were under proper medical treatment these persons were put to work. In this way the labor supply was conserved and the men were not refused the opportunity to earn a living because of their unfortunate infection. Of the total number of applicants accepted for employment 11 per cent. had marked physical disabilities, such as defects of sight, of hearing, of loss of fingers or of entire limbs. With proper attention to the placing of these individuals, practically no interference with efficient labor resulted.

Delousing.—As a result of the physical examination, 1,690 individuals were discovered to be infested with lice. The infested men were temporarily placed in a detention barracks, and then sent through the delousing house. Here they were subjected to a cleansing bath, medical inspection, and treatment. In the meantime, their clothing was run through the sterilizer. Their bed clothing was placed in a small air-tight building and subjected to cyanide fumigation.

It is of interest to note, however, that in spite of most rigid inspection and treatment, cases of pediculosis constantly escaped notice, to be discovered at a later date.

Vaccination and Typhoid Inoculation.—At the time of enrollment the men were vaccinated against smallpox and were also encouraged to receive typhoid inoculation. By means of the persistent health propaganda carried on, it has been possible to spread the knowledge of the value of these meas-

ures among those employed at this plant, with the result that 116,668 persons have received the prophylactic typhoid inoculation, and 76,920 persons smallpox vaccination. Owing to the many changes among the people employed at the plant, it was not possible to complete the course of treatment in many of these cases of typhoid inoculation. By far the great majority who remained at the plant have completed this treatment.

Hygiene of Housing.—During the period of construction practically all persons engaged at the plant were housed in barracks similar to those used by the Army during mobilization. These barracks number 27, and are 160 feet in length by 48 feet in width and 18 feet high, providing 7,680 square feet of floor space and 69,120 cubic feet of air to each floor. They are two stories in height, with 34 regulation windows on either side and 12 on the ends. They are equipped with 100 double-deck iron beds on the second floor, and 50 double-deck iron beds on the first floor, one-half of the first floor being used as a recreation room. These barracks house 300 men each. Twenty bunk houses, 120 feet long by 24 feet wide and 8 feet high, also offer facilities for sleeping quarters of the laborers. These are likewise equipped with double-deck beds.

Between each barracks building and bunk house is a bath house connecting with the barracks by a covered passageway.

Bungalow Housing.—Various employees, mostly administrative officers and office force, were housed in the bungalow section apart from the barracks section. The total number living under these conditions was relatively small at first, numbering possibly 1,500 persons, but later increased to approximately 10,000.

Medical and Surgical Relief.—Four six-bed emergency dressing stations were constructed in connection with the plant. In addition to this there was a 40-bed emergency hospital, an 80-bed isolation hospital, a 325-bed general hospital, and a dispensary in the bungalow section; the last named was for handling bungalow visits and giving dispensary service to the bungalow occupants. In addition to the relief of those actually ill or injured, medical relief was given those afflicted with disabilities, and to constructive and repair work in connection with eye, ear, nose and throat and dental affections.

Sanitation.—The problem of sanitation required both temporary and permanent measures. Under the former are embraced the measures taken to provide a safe disposal of excreta of the many thousand employees engaged in the construction of the plant; to maintain in sanitary conditions the stables for the several thousand horses and mules used in construction work; the provision of pure drinking water; the disposal of rubbish and garbage; the maintenance of sanitary kitchens and mess halls; inspection of all food—in short, such matters of general sanitation as generally arise in the maintenance of a large construction camp. Under the temporary measures, in order to furnish a safe water supply, a small chlorinating plant was installed, and several deep wells were drilled. From these water was delivered to the whole plant. Under the permanent sanitary measures may be enumerated provision of a safe water supply; construction and maintenance of an adequate sewerage system and sewage disposal; inauguration of a system of street cleaning, including garbage and refuse collection and disposal; establishment of a system of food supervision.

A permanent water system was installed with necessary filters to supply a city of 35,000 population, and chemical and bacteriological analyses of this water were made daily in the laboratories at the hospital.

All food entering the plant was shipped to the Commissary Warehouses and refrigerating plant, and there inspected by the food inspectors, and likewise again inspected in the commissary stores and mess halls before being consumed.

Occupational Health Hazards.—The gradual completion of the plant witnessed the inauguration of the industrial operation for which the plant was established, that is, the production of smokeless powder. Some of the health hazards met with during operation are as follows: Nitric and sulphuric acid burns, caustic alkali burns, the inhalation of nitrous and sulphuric fumes and of chlorine, excessive heat and humidity, alcohol and ether intoxication, poisoning by diphenylamine, and burns from a flare or sudden burning of powder. In order to lessen these hazards an educational campaign was conducted by medical officers instructing the workmen in the dangers and the first-aid treatment to be employed. One hundred and twenty-five stretcher outfits, containing each one stretcher and one blanket, were scattered through the plant, being easily accessible to those who might be injured, and the nearness of the field emergency stations made it possible to render medical service almost immediately upon the occurrence of an accident. Three motor ambulances were stationed at the emergency hospital, having free access to all parts of the reservation. First-aid boxes were installed in all places deemed advisable for immediate relief, and shower-bath facilities were installed in the acid area for bad acid burns.

SCIENTIFIC RESEARCH.

Industrial Fatigue.—With the necessity imposed by the war to conduct its industrial operations at the highest possible degree of efficiency, the Public Health Service at once became vitally interested in the relation of industrial fatigue to efficiency. In cooperation with the divisional committee on industrial fatigue of the Council of National Defense, the Service in the summer of 1917 began an extensive investigation of this important health problem.

While a considerable number of factories were visited, detailed studies were limited to two large establishments which offered exceptional opportunities for observation. One of the main objects in view was the determination of the conditions under which the operatives, the human machines of the factory, can perform their work with the highest degree of efficiency. The subjects considered included output, night work, effect of recess periods, accidents, and physiological tests for fatigue. A summary of the results of these studies was published in the annual report of the Public Health Service for the fiscal year ending June 30, 1918.

Trinitrotoluol Poisoning.—At the Hygienic Laboratory systematic studies were commenced in regard to the methods of absorption, detection, and preven-

tion of trinitrotoluol poisoning. These studies are expected to be of great assistance in providing sanitary requirements which will minimize the danger from trinitrotoluol, a substance which is used principally as a charge in high-explosive shells. The manufacture of trinitrotoluol is surrounded with considerable risk of poisoning.

The investigation related to:

1. Simple diagnostic tests for the recognition of early poisoning.
2. A preventive skin wash for the efficient removal of TNT.
3. The relative importance of absorption of the poison through the skin and the respiratory passages.
4. The prophylactic value of proper diet.
5. The incidence of poisoning in one of the larger shell-loading plants.

Nutritive Value of Various Kinds of Flour and Bread.—At the Hygienic Laboratory an extensive investigation covering a period of nearly two years has shown that highly milled flour and bread made from this flour are considerably inferior in vitamine content to the "low extraction" flours now so extensively used in European countries. This conclusion was reached from well-planned feeding experiments on animals, in which all extraneous and complicating factors were eliminated. One of the main objections against the "low extraction" flour, namely, its excessive cellulose content, could easily be overcome by a method of milling which would permit the elimination of a greater part of the bran.

Influence of Heat on the Vitamine Content of Beef.—Another investigation bearing quite directly on war matters was one carried on by the Hygienic Laboratory to determine whether the canning process robbed meat of the so-called vitamine present in fresh meat. The work has conclusively shown that under ordinary conditions beef does not lose any of its vitamine content when heated for three hours to 120 deg. C.

Studies on Dermatitis from Mercury Fulminate and Parazol.—At the request of the Ordnance Department of the Army and of the United States Navy an investigation was undertaken to devise means of preventing the severe dermatitis which results from mercury fulminate and parazol respectively. A protective skin varnish against parazol was developed.

Antitoxin Against Gas Gangrene.—The Hygienic Laboratory was called upon to prepare and standardize an antitoxin against gas gangrene. Considerable work on gas gangrene has been done by investigators abroad, but no definite results have been obtained. The studies conducted by the Hygienic Laboratory resulted in a method of standardization for perfringens antitoxin for gas gangrene.

Laboratory Studies on Arsphenamine.—Up to the time of the outbreak of the war, arsphenamine (salvarsan) was exclusively manufactured in Germany and was protected by patents in most countries. As a result of the war the supply in the United States was seriously reduced, particularly on account of the blockade, which made it impossible to secure enough of the German product. In 1916 a few private institutions began the manufacture of arsphenamine in the United States, under an agreement with the Farbwerke Hoechst Company, the German holders of the patent in this country. Soon after the declaration of war by the United States the patent on salvarsan was suspended and the Federal Trade Commission was authorized by Congress to issue licenses for the manufacture and sale of the drug. The manufacture of arsphenamine is extremely difficult and results very often in a product of high toxicity which is dangerous to the life of the patient. Hence it is absolutely essential to control the commercial product by proper toxicity tests before the drug is released for sale to the medical profession. These circumstances therefore necessitated the adoption of a satisfactory method for this purpose, and after considerable work such a method was developed. Standards of toxicity for arsphenamine, submitted to the Federal Trade Commission, were accepted and the manufacturer was required to test his product by means of the method developed at the Hygienic Laboratory. This laboratory furthermore controlled the commercial product by testing many hundred samples submitted by the manufacturer. In addition to the toxicological tests, chemical standards were worked out so as to insure, as much as possible, uniformity in the therapeutic value of the drug.

An investigation was conducted into the process of manufacture of arsphenamine. The work was done at the Hygienic Laboratory, the University of Chicago, and at one of the larger plants where arsphenamine was produced. This led to marked improvement in the quality of this particular brand of arsphenamine and removed the serious shortage of the drug at the beginning of the year 1918. As a result of this work the army and navy were able to secure a sufficient supply of the drug.

Another phase of the arsphenamine work had for its purpose the elimination of the untoward reactions sometimes following the administration of the drug to patients. It appeared particularly important to determine the causes of these reactions and to discover means for their prevention and treatment. The work was divided into:

1. A study of the cause of the circulatory and respiratory reactions (nitritoid crises).
2. The study of arsphenamine nephritis. Considerable progress has been made on this subject and upon completion of the work it is hoped that certain definite recommendations will be available which will eliminate some of the disadvantages possessed by this drug and prevent the small number of deaths resulting from its use.

Miscellaneous Laboratory Examinations.—In connection with the rumors that many kinds of contaminations, poisons and glass were being introduced into food by enemy sympathizers, the Hygienic Laboratory examined specimens from suspicious cases submitted by officers of the Government. The specimens covered an exceedingly wide range of objects, such as candy, cakes, bread, pies, breakfast foods, and dried and preserved fruits. The most interesting of these specimens were those of court plaster, sent to the laboratory because it was suspected by the general public that German

agents had introduced tetanus bacilli into the court plaster and then had peddled the plaster to the public. Thirteen samples of the suspected court plaster were examined and tetanus bacilli were found in two samples. This was so interesting that the laboratory deemed it advisable to go into these investigations more thoroughly. Accordingly, numerous samples of court plaster were purchased in drug stores in the open market and submitted to examination. The result showed that a number of the specimens contained tetanus bacilli and that the presence of these bacilli was due to insufficient sterilization of the gelatin used in the plaster. Regulations were accordingly framed governing the sterilization of gelatin used in the manufacture of court plaster.

Another interesting case was the appearance of anthrax in several cantonments among the users of new shaving brushes. Several soldiers who had purchased new shaving brushes developed anthrax with fatal results. The brushes which they used were submitted to the Hygienic Laboratory and the examination showed the presence of anthrax spores in the bristles. The manufacturers of the various brushes were communicated with and their cooperation was secured in solving this interesting problem. It appeared that the bristles used in the manufacture of shaving brushes are to a large extent imported from China. It further appeared that although the bristles were cleansed by ordinary scrubbing, they were not really sterilized. Under these circumstances it is readily seen that anthrax infection in an animal whose bristles were used for shaving brushes could be transferred to the user of the shaving brush. Regulations governing the sterilization of bristles used in the shaving brushes were prepared under the authority of the Interstate Quarantine Act.

PRODUCTION AND SUPERVISION OF BIOLOGICAL PRODUCTS.

The entry of America into the war resulted in an enormous increase in the production and use of serums, toxins, and analogous products. As all manufacturers of these products are licensed by the Federal Government and as the law provides for the examination and control of the products and for the inspection of the manufactories, an immensely increased amount of work was thrown upon the Hygienic Laboratory. It was particularly necessary that every lot should be tested before being released for use in the Army or the Navy, as these two services depended entirely upon the reports of tests made at this institution. Promptness was an important factor. The outbreak of meningitis and pneumonia in the military camps was the signal for using vast quantities of specific sera for these infections. These sera were standardized in the Hygienic Laboratory, and manufacturers were instructed to comply with these tentative standards.

In order to help protect the military forces against typhoid fever considerable attention was devoted to the control and eradication of typhoid infection from extra-cantonment areas. In this work extensive use was made of antityphoid inoculations. The vaccine for this purpose was prepared and furnished by the Hygienic Laboratory. In this connection the following table will be of interest:

Production of Typhoid Vaccine.

Fiscal year ending June 30, 1914.....	4,892 cc. produced
Fiscal year ending June 30, 1915.....	17,248 cc. produced
Fiscal year ending June 30, 1916.....	16,075 cc. produced
Fiscal year ending June 30, 1917.....	99,889 cc. produced
Fiscal year ending June 30, 1918.....348,275 cc. produced	
July 1st to Dec. 1st, 1918.....612,908 cc. produced	

During the period of the war 1,102,812 c.c. of bacterial vaccine were distributed. This includes typhoid, paratyphoid, and the so-called "triple vaccine." The manufacture of the last-named was begun in 1917.

CAMPAIGN AGAINST VENEREAL DISEASES.

Inasmuch as venereal infection had regularly exacted a heavy toll from military forces, and because experience had shown that the source of this infection was principally an infected civilian population, the outbreak of the war naturally focused the attention of civilian health authorities on the control of venereal diseases to the end that the military forces might be protected. Prior to the war a number of progressive States had begun to deal with this problem, and in general the result of their activities had demonstrated a practicable plan by which health authorities might hope to secure some measure of control of the venereal diseases. There was lacking, however, any nationwide interest in this important health problem, and, still more important, very little disposition on the part of most State authorities to provide funds for anything approaching an adequate plan of control.

Charged as it is with the control and prevention of communicable diseases spread from State to State, the Public Health Service realized that it had a definite responsibility in organizing an effective campaign for the control of venereal diseases.

Accordingly, through its division of domestic quarantine it outlined a plan whereby the Public Health Service would cooperate with State health authorities in effective anti-venereal disease control. Briefly summarized, the plan provided for the appointment of an officer in each State to direct the work of venereal disease control. The salary of such officer, selected by the State health officer, was to be paid by the State and Federal governments jointly. Each State was at once to provide for the notification of all cases of venereal disease, and to make provision for the extension of facilities for early diagnosis and treatment. Repressive measures, looking to isolation and treatment of dangerously infected individuals, and educational measures for the general public as well as for the infected persons, were also to be provided for.

Under the stimulus of the war emergency a considerable number of States accepted the plan of cooperation just outlined. Nevertheless it is certain that nowhere near the progress that actually has been made would have been made had it not been for the Federal financial aid given by the so-called Chamberlain-Kahn act approved July 9, 1918.

Under the provisions of this act allotments were made to each of the various States. Such allotments were to be expended in accordance with the rules and regulations promulgated by the Secretary of the Treasury. These provide that approximately 50 per cent. of the State's allotment is to be used in treatment of venereal diseases; 20 per cent. for the educational work; 20 per cent for law enforcement, and 10 per cent. for administration.

At the present time venereal disease clinics are being conducted in 28 extra-cantonment zones, and 112 in other locations. During the period of one year—1918—22,441 cases of venereal diseases were treated in the extra-cantonment clinics. These cases were divided as follows: syphilis, 9,250; gonorrhea, 12,210; chancroid, 981. At each of these clinics a circular is handed to the patients, giving important confidential information in regard to syphilis and gonorrhea.

At the time of the second draft the Provost Marshal General of the Army requested the Public Health Service to carry on a campaign of education among the drafted men. Lecturers were appointed and nine regional supervisors were placed on the road to supervise this lecture work. Three million copies of the leaflet entitled "Come Clean" were printed and distributed to the men in Class A.

The moving picture film "Fit to Fight" prepared by the Army Medical Department has been revised and the title changed to "Fit to Win" and is being shown before civilian audiences throughout the country.

A circular letter was sent to all of the retail druggists in the United States (about 47,000) asking that they discontinue the sale of venereal disease nostrums and cease counter-prescribing for venereal infections. A bulletin entitled "Responsibility of Druggists for the Public Health" was also sent to each of these druggists.

A circular letter will soon be sent to all of the physicians in the United States, asking that they cooperate in the fight against venereal diseases. This is Venereal Disease Circular No. 35. Seventy thousand copies of the Manual for the Treatment of Venereal Diseases are now in the hands of the printer and will be sent free of charge to each physician that replies to this appeal.

More than 17,000 letters have been received by the Bureau as a result of the circular "War on Venereal Diseases to Continue". Out of this total number, only four contained adverse criticisms. All of the other letters received showed a deep interest and sympathy with the movement for control of venereal diseases throughout the country.

Following is a list showing the allotments made under the provisions of the Chamberlain-Kahn Act. Each of the States has received the allotment, with the exception of those marked with a star:

Alabama	$23,247.41	Massachusetts	$36,603.94
Arkansas	17,117.43	Nebraska	12,962.79
Arizona	2,221.95	*New Mexico	3,558.74
California	25,851.07	Nevada	890.22
Colorado	8,687.79	North Dakota	6,274.30
Connecticut	12,120.75	North Carolina	23,988.94
Delaware	2,199.84	New Hampshire	4,681.62
*Dist. of Columbia.	3,598.72	New York	99,089.31
Florida	8,182.47	Oregon	7,315.04
Georgia	28,368.95	Ohio	51,832.61
*Idaho	3,540.19	Oklahoma	18,017.23
Indiana	29,366.62	*Pennsylvania	83,342.76
Illinois	61,308.38	Rhode Island	5,899.80
Iowa	24,194.56	South Dakota	6,348.61
Kentucky	24,898.14	South Carolina	16,476.95
Kansas	18,385.49	*Tennessee	23,755.21
Louisiana	18,008.89	Texas	42,367.08
Montana	4,088.71	*Utah	4,059.33
Michigan	30,555.01	Virginia	22,415.90

MEDICAL AND SURGICAL RELIEF.

War Work of the Marine Hospitals.—The Executive Order of the President dated April 3, 1917, made all marine hospitals of the Public Health Service available for the treatment of the enlisted personnel and officers of the Army and Navy whenever such treatment was requested by the proper military authorities. Of course the Army and Navy have their own hospitals, but it was expected that in many places where there is no regular military post or hospital, officers and enlisted men would be taken sick and require hospital treatment. In this way the marine hospitals practically acted as military hospitals in many cities. Notable examples of this are Savannah, Detroit, and Chicago. Besides Army and Navy personnel, civilian employees on vessels operated by the military authorities were admitted at many hospitals after the boats upon which they served had been torpedoed. This occurred especially at the marine hospital in Boston. Altogether, for the fiscal year ending June 30, 1918, there were treated at the United States Marine Hospitals and relief stations over 5,000 officers and enlisted men of the Army and Navy. Of this number approximately 1,000 were admitted to hospital for treatment, the remainder having been given treatment as out-patients in the dispensaries operated either in connection with the hospitals themselves or at other relief stations.

In addition to the foregoing, soldiers suffering from trachoma were admitted to some of the marine hospitals for treatment and in the majority of instances these were cured and returned to their respective commands.

Cooperation with Bureau of War Risk Insurance.—A direct outgrowth of the war activities of the Public Health Service is the plan to provide medical, hospital and sanatorium care for the beneficiaries of the Bureau of War Risk Insurance.

Already, with demobilization just begun, the War Risk Insurance Bureau has under medical treatment 1,724 beneficiaries (January 16, 1919).

Within a very short time hospital care will have to be provided for a considerable proportion of the 24,500 soldiers, sailors and marines discharged from military service because of tuberculosis, and for the 50,000 cases of psycho-neurosis, epilepsy, and other nervous and mental disorders reported among the military forces up to December 1, 1918. But this by no means exhausts the demands for hospital care which may be expected to be made upon the Public Health Service. According to the provisions of the War Risk Insurance Act the Government is obligated to provide "such reasonable governmental medical, surgical and hospital services, and with such supplies including artificial limbs, trusses and similar appliances as the director may determine to be useful and reasonably necessary." The application of such sick benefits is limited to illness contracted in line of duty, and it is further provided that symptoms must have appeared within a year after discharge from military service. In order to prevent the unnecessary duplication of hospital construction by various bureaus and departments of the Federal Government, the suggestion was made that the hospitals in the present cantonments be utilized for the care of beneficiaries of the War Risk Insurance. In a bill recently passed by Congress, certain cantonment hospitals, together with the large and newly completed "Speedway" hospital in Chicago, are given over to the Public Health Service for

the care of War Risk patients. In addition to this the bill provides for the establishment of sanatoria for the tuberculous in various parts of the country.

There is an advantage in having the hospital activities of the War Risk Insurance conducted by the United States Public Health Service: both services are lodged in the Treasury Department, and the Public Health Service already maintains a well-organized hospital service which, by law, stands obligated to treat.

1—Merchant seamen.
2—Employees of the Mississippi River Commission.
3—The United States Coast Guard Service.
4—The United States Lighthouse Service.
5—Employees aboard vessels of the Engineer Corps of the U. S. Army.
6—The United States Coast and Geodetic Survey.
7—Injured civil employees of the United States, under the Federal Compensation Act.
8—Civil employees on Army transports.

MISCELLANEOUS ACTIVITIES.

Sanitary Engineering.—The sudden development of industrial towns and villages in connection with munition plants, shipyards and the like resulted in a considerable number of requests to the Public Health Service for assistance in the solution of problems relating to water supply, sewage disposal and the like. Some idea of the character of the activities thus carried on by the Service may be gained from the following examples:

The citizens of Nashville, Tenn., became somewhat alarmed over the safety of their water supply when it was decided to locate a large government explosives works on the Cumberland River, about 12 miles above the city. An investigation was made by the Public Health Service and a report submitted, including suitable recommendations for the disposal of sewage at the Government plant and for necessary additional safeguards to the water supply. Later, the question of the discharge of waste acid liquors into the Cumberland River was raised, and a board was appointed to consider this matter. Extensive studies were made and a remedial plan worked out.

The attempt on the part of the City of Petersburg, Va., to furnish water to Camp Lee led to a shortage in the supply and inadequacy of treatment. An officer of the Service investigated this situation and made recommendations toward general improvement of the supply. The city having declined to make the necessary changes this matter was later referred to the War Department, which assumed charge of the entire water works.

Shortly after the signing of the armistice serious complaint arose in Milwaukee, Wis., over the alleged pollution of the drinking water by a phenol plant located south of the city and discharging wastes into the lake about 12 miles from the water works intake. Investigation by the Service showed that the complaints were well founded. Recommendations were made that the matter be referred to the War Department, and that the contract under which the plant was operating be canceled. The operation of this plant was discontinued very shortly thereafter.

At the request of the Navy Department a visit of inspection was made to the Marine Camp, Quantico, Va., and a report with recommendations was subsequently submitted, with reference to the proper treatment and disposal of sewage of the camp.

A small factory at Gaithersburg, Md., engaged in canning beans for the War Department, had failed to provide proper means of disposal for its waste water and was seriously polluting a small stream. Complaints of nuisance in the town and of the poisoning of cattle were pressed and the closing down of the factory was seriously threatened. An investigation made by the Service resulted in the construction of some temporary works which greatly relieved the situation and made it possible to continue the factory in operation throughout the remainder of the season.

In connection with Service activities at Newport News, the importance of milk pasteurization led to the study of the possibilities of a central pasteurizing plant for that city. An officer of the Service who had already made similar studies for Tuscaloosa, Ala., was assigned to this study and prepared complete plans and in part supervised the installation of this pasteurizing plant. The plant at this time is complete and in operation under the general supervision of the Service.

A similar need for a satisfactory milk supply having arisen at the Government powder plant at Nitro, W. Va., plans were originally prepared for a pasteurization plant, but it was later decided to undertake at that point a demonstration of the possibilities of reconstructed milk. An officer of the Public Health Service accordingly prepared plans and supervised the construction of this plant. The operation has been most satisfactory, and an abundant supply of clean and wholesome milk was assured the city at a price considerably lower than normal city prices at this time.

Cooperation with Other Government Agencies.—Council of National Defense, War Industries Board, Capital Issues Committee.—Actuated as it was by the desire to do all in its power to insure the success of the nation's great undertaking, the Public Health Service gave freely of its services to other Government departments and to agencies engaged in war work. Mention has already been made of the cooperation with the military authorities and the American Red Cross in the sanitation of extracantonment areas and of the cooperation with the Bureau of War Risk Insurance in providing medical and surgical care for beneficiaries of the insurance fund. The Public Health Service also cooperated with the Council of National Defense, in the Medical Section of which the Surgeon General served as chairman of the Committee on Hygiene and Sanitation. In the Council's Section on Labor, the Public Health Service took an active part in matters relating to industrial hygiene; with the National Research Council it cooperated in a number of scientific investigations, and it furnished expert advice as to the health needs of civilian communities to the Priorities Committee of the War

Industries Board and to the Capital Issues Committee.

United States Navy.—An important war activity of the Public Health Service was its cooperation with the Navy Department.

For the purpose of assisting in the protection of health of the Navy and thus aid in increasing the efficiency of the Navy as a fighting force, a medical officer of the Public Health Service was detailed as Sanitation Officer to each of the fourteen naval districts in the United States.

In general the duties of these officers embraced the following:

1. To make regular inspections of the sanitary conditions of the naval stations and all places within the Naval Districts to which they are assigned, with special reference to water supplies, sewage, garbage and manure disposal, introduction, presence and disposition of cases of communicable diseases, the presence of disease-carrying insects, or of conditions favoring their growth, and to the facilities for messing and housing the personnel.
2. To secure information by personal observation and through civilian health authorities as to the prevalence of communicable diseases and sanitary conditions in the areas around naval stations and in localities from which recruits are collected.
3. To advise and assist in eradicating any communicable disease that may make its appearance in the district, and to make such epidemiological investigations as may be necessary and practicable.
4. To secure information as to the quality of water and milk supplied to both naval forces and civil population in the immediate environments of camps and stations, and as to methods of disposal of sewage, etc., in such localities.
5. To pay particular attention to the presence of disease-bearing and other mosquito-breeding areas either within the camp or within its immediate environment.
6. To determine as far as practicable the prevalence of venereal diseases in the civil communities adjacent to camps and stations, and the measures used for their control.
7. To make monthly inspection of the industrial establishments in the navy yards and make suitable recommendations, when necessary, for the correction of insanitary and un-hygienic conditions.

Additional activities were undertaken as the needs arose. In the New York Naval District, for example, these included the inspection of various shipyards in the neighborhood where navy yard personnel was employed, the inspection of ships belonging to the transport cruiser force, and the fumigation of these vessels by the navy personnel under the direction of the Sanitation Officer.

PUBLICATIONS RELATING TO WAR ACTIVITIES.

An important function of the Public Health Service is the dissemination of information regarding public health matters. The following list of articles published by the Service gives such a good idea of the war activities of the Public Health Service that its publication here may be of interest:

Trachoma and the Army—The Dangers Incident to Enlisting Recruits Affected with the Disease. By John McMullen.

Meningococcus Carriers — Their Recognition and Treatment.

Certain Military Aspects of Hookworm Disease. By Ch. Wardell Stiles.

The Lighting of Industrial Establishments—The Need for Supervision, with Suggested System of Maintenance Rating for Artificial Light Equipment. By Davis H. Tuck.

The Simulation of Disease—Drugs, Chemicals, and Septic Materials Used Therefor. By A. G. DuMez.

Trinitrotoluol—Practical Points in Its Safe Handling. By J. W. Schereschewsky.

Mitigation of the Heat Hazard in Industries. By J. A. Watkins.

Extra-Cantonment Zone Sanitation—Camp Shelby, near Hattiesburg, Miss. By J. A. Watkins.

Industrial Efficiency—The Bearings of Physiological Science Thereon—A Review of Recent Work. By Frederic S. Lee.

Morbidity Statistics of War Industries Needed. By B. S. Warren.

A State-wide Plan for the Prevention of Venereal Disease. By Allan J. McLaughlin.

Extra-Cantonment Zone Sanitation, Newport News, Va., and Vicinity. By S. B. Grubbs.

Methods for Field Study of Industrial Fatigue. By P. Sargeant Florence.

Suggestions for State Board of Health Regulations for the Prevention of Venereal Diseases.

The Present Status of Our Knowledge of Fatigue Products. By Ernest L. Scott.

Progress in Venereal Disease Control. By J. G. Wilson.

The Dietary Deficiency of Cereal Foods with Reference to Their Content in "Anti-neuritic Vitamine." By Carl Voegtlin, G. C. Lake, C. N. Myers.

The Growth-Promoting Properties of Foods Derived from Corn and Wheat. By Carl Voegtlin and C. N. Myers.

Phosphorus as an Indicator of the "Vitamine," Content of Corn and Wheat. By Carl Voegtlin and C. N. Myers.

Some Qualitative and Quantitative Tests for Arsphenamine. By C. N. Myers and A. G. DuMez.

Dried Milk Powder—A Review of British Experience.

State and Federal Co-operation in Combating the Venereal Diseases. By J. G. Wilson.

Control of Diseases in Establishments for the Manufacture and Loading of High Explosives. Report of Divisional Committee on Industrial Diseases, Section of Sanitation, of the Committee on Labor, Council of National Defense.

Venereal Disease Control—Standards for Discharge of Carriers.

Regulations—Promulgated by the Secretary of the Treasury, under which State Boards of State Departments of Health Receive the Allotment of Funds provided in Section 6, Chapter XV, of the Act Approved July 9, Entitled "An Act Making Appropriations for the Support of the Army for the Fiscal Year Ending June 30, 1919."

War Program of the Public Health Service—Intended Especially for Extra-Cantonment Areas and War Industrial Centers.

Sanitation of Rural Workmen's Areas—With Special Reference to Housing. Report of Divisional Committee on Village and Public Sanitation, Section of Sanitation, Committee on Welfare Work of the Committee on Labor, Advisory Commission, Council of National Defense.

Preliminary Report on Carbon Tetrachloride Vapor as a Delousing Agent. By H. M. Foster.

Maintenance of Health in Industries—Its Relation to the Ac uate Production of War Materials.

Extra-Cantonment Zone Regulations — Regulations Governing the Sale of Food and Drink in the Special Sanitary Zone Around Camp Pike, near Little Rock, Ark.

Tetanus in Court-plaster—Results of the Bacteriological Examination of Fourteen Specimens.

Diphtheria, an Epidemic, Probably of Milk Origin, Occurring at Newport, R. I., and Vicinity.

Arsphenamine (Salvarsan) Licenses Ordered and Rules and Standards Prescribed for Its Manufacture.

Venereal Disease Legislation—A Compilation of Laws and Regulations Showing the Trend of Modern Legislation for the Control of Venereal Diseases.

Physical Fatigue as a Factor in Increasing Susceptibility to Communicable Disease.

Anthrax from Shaving Brushes.

Industrial Fatigue—Investigation by Means of Factory Statistics.

The Reserve of the Public Health Service.

MEDICAL RECORD.

New York, May 24, 1919.

EVOLUTION AND PROGNOSIS OF SPOROTRICHOSIS.

SPOROTRICHOSIS undergoes a slow, painless evolution, without a rise in temperature excepting in a few rare exceptions in which the lesions are painful. The general health remains good, the patient being disturbed only by the annoyance caused by the lesions when movements are made, and for this reason the case comes up for treatment only when the gummata have attained considerable size or have ulcerated. In almost all cases there is a history of bronchitis or of grippe which occurred before the appearance of the gummata, but it is questionable if these pulmonary affections have any relation to the sporotrichosis. The duration of the evolution varies anywhére from two to six months, hardly ever longer. It progresses in successive attacks and thus can be explained the great variety of lesions presented by the patient. Trauma favors the evolution in several ways, either by creating an entrance for the fungus into the organism or by producing a point of lessened resistance. In the latter case, infection is supposed to have already taken place. The infection extends by either the lymphatics or the general circulation. If inoculation takes place in a wound the lymphatic route is followed, while when inoculation occurs on a mucous surface the infection is carried by the blood.

The prognosis of sporotrichosis is not serious, especially now that its treatment with the iodides has come into practice. Fatal cases have indeed been recorded, but they are few in number. The nature of the soil explains certain serious types of the disease, while an absence of immunity explains recurrences. The sporotrichum is a parasite of low virulence, but it can produce lesions of marked intensity. There are three factors by which this discordancy can be explained, namely, a diminution of the patient's resistance, an increase in the virulence of the fungus, and a progressive sensibilization of the individual. The soil is favorable for the parasite when the subject is an alcoholic, diabetic, or arthritic. The fungus becomes progressively more virulent, a fact well demonstrated by experimental work in animals. This also explains the aggravated nature of the lesions and their greater gravity as new attacks succeed each other when left untreated. The greater the number of gummata the more sensible will the patient become to the propagation of the fungus.

The exhibition of the iodides should be continued for several months after all the morbid manifestations have completely disappeared, because if treatment is suspended too soon the manifestations of the fungus will recur with an increased intensity. Fortunately, in the iodides we have an absolute specific, and a properly conducted exhibition of the drug will result in a cure of the process within a month or six weeks, but we would repeat that it must be continued for some months after all morbid manifestations have disappeared, otherwise a recurrence in an aggravated form is sure to occur. Although the affection is characterized by subcutaneous gummata disseminated over the body surface, it should be recalled that the muscles, bones, and viscera may not escape involvement, another and very good reason for continuing treatment after the cutaneous lesions have retrogressed.

STRAINS OF VARIOLA.

THE reports to the British Local Government Board on Public Health and Medical Subjects frequently contain material of very great value. Dr. R. Bruce Low has recently supplied information of this character to these reports in his elaborate review of the "incidence of smallpox throughout the world," which is discussed at some length in the *Tropical Disease Bulletin*, March 15, 1919. In the course of the review he states that the strains of smallpox infection current in different parts of the world vary in their degree of violence; those in Asia and Africa sometimes being more serious than those met with in North America, or in the recent epidemics in Australia and New Zealand, where frequently, even in unvaccinated people, the disease has been of a mild clinical type with few serious sequelæ. With regard to Australia Dr. Bruce Low's figures show that in seven epidemics ranging from 1868 to 1903 in that country, there was no indication of special mildness; in four years the case mortality per cent. was from 17.3 to 28.8 and in three years from 2.59 to 10.7. In 1913-1914, however, in New South Wales there occurred 1,661 cases of smallpox of a type so mild that at first it was confused with varicella. It was believed this strain was introduced from Vancouver, and that it was of the same character as one causing an endemic long known to prevail in Canada and the United States. In New Zealand in the same period this mild type became epidemic, the chief sufferers being the Maoris. A similar mild type is reported to have been experienced in Venezuela, Barbados, St. Vincent, Grenada, Tobago, and Demerara. In South Africa an apparently similar form of the malady is known by the term "amaas" or "Kaffir smallpox."

The writer, in referring to the mild type

occurring in America, points out that while the benign form is the prevailing type, other and more virulent strains of infection are occasionally imported into the United States, notably from Mexico, and give rise to fatal outbreaks, spreading in virulent form unless energetically dealt with. It has also to be kept in mind that even when the strain of infection is benign some of the persons attacked by it occasionally, under conditions as yet not quite clear, develop a virulent form of the disease. As for example Assistant Surgeon Eskey, U. S. Public Health Service reported in *Public Health Reports*, September 20, 1918, that at Eagle Pass, Texas, both virulent and mild smallpox had been present during the epidemic that prevailed there. Mild cases occurred among those unvaccinated as well as sometimes among those with vaccination scars. The virulence decreased as the epidemic progressed, the number of deaths in the first ninety cases being 27, or 30 per cent., and in the last 60 cases 6, or 10 per cent.

Those who have studied the cultivation of animal vaccine on the calf, have had it forced upon them that strains of vaccine have as definite an existence as breeds and varieties of breeds of horses. Each has its characteristics, which can be maintained so long as conditions attending transfer from animal to animal are practically the same. It seems evident, arguing from analogy, that there also exist strains of smallpox which pass from human being to human being of different races, and under varying climatic conditions and yet remain, in at least the greater number of attacks, true to type, although liable in individual cases to the exhibition of increased or decreased vigor.

HAS SPINAL ANESTHESIA ESTABLISHED ITSELF?

THAT the affairs of men have a rhythmical tendency has arrived at the status of an axiom. Reaction is equal to action, and even greater, as David Harum might have said in another sphere. A little-heeded novelist dies and the public rush to deck his tomb, and buy his books, and a few years later callous critics dip their pens and automatically inscribe their standard exordium: "Now that we are beginning to get the proper perspective on the works of So-and-So it becomes doubtful whether—" and follow by the style of carping harmonious to the public's then mind. This swing of the pendulum backward and forward is seen in medicine as in other human activities. A new therapy is introduced, becomes popular, and is recommended for an extensive list of ailments. Then failures and disadvantages are noted and articles begin to appear questioning whether there is any worth in the method whatever. Later on, as the pendulum vibrates with less and less amplitude, the treatment begins to find its true place in medicine.

Quite often the introduction of a new drug or diagnostic method to the profession is associated with some picturesque or forceful personality whose enthusiasm and weight carry it too far; later he partakes of the reaction, or if perchance he loses caste for some other reason, the innovation he sponsored shares in his downfall. Many instances might be cited in exemplification, but we have in mind just now spinal anesthesia, which enjoyed such a vogue a few years ago, in the peace and quiet of the antebellum days. This method had, according to its advocates, all the merits and none of the drawbacks of general anesthesia by inhalation. Then reports of an occasional death began to mar the serenity of the picture. Soon the succinct criticism "unsafe" attached itself to spinal anesthesia and its day was done.

It may be a matter of speculation, however, to the thinking few whether such a sweeping rejection of a method which certainly had its advantages was justified or not. This question was investigated a few months ago by an English writer, Dr. Rood (*The Lancet*, January 4, 1919), who has been at considerable pains to present the true status of spinal anesthesia without bias. Dr. Rood does not go into the technique, except to say that he uses stovaine, a five per cent. solution, for the most part, novocaine only occasionally. He has had two deaths in eight thousand cases, an experience which compares favorably with any method. He recommends using it in hospitals even where there is no especial indication for its use, *i.e.* in ordinary cases of appendicitis, hernia, and the like, so that the necessary skill may be acquired in its use when indicated. With such skill and ordinary care Rood believes that it is as safe as other methods; he has never seen a death from its use in any simple operation and he has seen many lives saved by it. His conclusion is that spinal anesthesia is past the experimental stage and, while not to be considered a universal anesthetic, and while possessing certain dangers, it has such decided merits that it should be used in suitable cases in all hospitals.

THE PLAGUE EPIDEMIC IN INDIA.

INDIA has been visited repeatedly by the plague during the past two decades, but at present there are evident signs that these periodical epidemic outbursts are permanently abating in virulence. Direct experimental investigation has shown that the newer generations of rats are developing comparative immunity from infection of the disease and that it is quite probable that in time the rats in long-infected districts may become absolutely immune. That this would probably be the ultimate outcome of the plague in India was always predicted by Dr. C. J. Martin, F.R.S., the director of The Lister Institute, who organized the remarkable and extensive series of researches which demonstrated that the infection was conveyed by rat-fleas from rat to man. Dr. Martin's first inquiries into the plague were made in 1897, and his theory now seems to be in process of becoming accepted.

There can be little, if any, doubt that it was in some similar fashion that the plague ultimately disappeared from the British Isles. The supposition is that the Black Death of 1348 and all the successive epidemics down to the Great Plague of London in 1665, were frequently dual in character. They were probably in part bubonic and in part pneumonic. This latter type of plague is conveyed by direct infection from man to man and is characterized by short virulent outbreaks which quickly subside, as in Manchuria some years ago. In bubonic plague the contagion is carried by the rat-flea, and it is suspected, although the inference cannot be directly proved, that the British rats gradually and progressively became immune to plague infection, and it is perchance not impossible that their comparative immunity still continues.

The plague has unquestionably remained persistently endemic through centuries in certain remote parts of the world, such as the highlands of Yun Nan in China, and in Western Arabia. Major Norman White of the India Medical Service, in an official report to the Government of India, warns that country that it is still "by far the most important reservoir of plague in the world." So recently as 1917-18 the peninsula suffered from an abnormally severe epidemic, which extended to towns never before infected. During the last two decades it has taken a toll in India alone of ten million lives, and yet Major White declares with truth that "of all preventable diseases, none is more preventable than bubonic plague." In several years during the two decades the mortality from the plague far exceeded that from cholera, which in the present state of our knowledge should be regarded as almost equally preventable.

Gunshot Wounds of the Pancreas.

It has been for long the general belief that acute disease of the pancreas is very fatal. Mr. Gordon Taylor, writing in the *Clinical Journal* of April, 1919, points out that in cases of injury to this organ the prewar literature does not altogether take this pessimistic view. Taylor said it was a matter of some interest to him on going to France to learn of the reputed very fatal nature of injury to this organ. Attention has been drawn to the fact that in the war gunshot wounds of the pancreas were less frequent, or at any rate less often recognized than those of any of the other abdominal viscera, and it has been explained that the intimate relations of the gland to the large blood vessels are such that a wound of the pancreas involves the greatest risk of an immediate and probably fatal hemorrhage, so that many such cases did not reach the casualty clearing hospital. In General Cuthbert Wallace's series of 965 operated cases, described in his "War Surgery of the Abdomen," the pancreas is noted as wounded in only five, and in but one of these was the patient evacuated successfully. Sir G. Makin's results were much the same. Judging from his own experience and that of others Taylor comes to the conclusion that in the recent war gunshot wounds of the pancreas have indeed been fatal injuries, and the few successful cases recorded are to be regarded as exceptional.

Poisoning with Oil of Chenopodium.

This subject is of interest to the miscellaneous reader because of the recommendation of the remedy for uncinariasis as a substitute of thymol. In the *Correspondenz-Blatt für Schweizer Aerzte* for March 22, Ryhiner, of Professor Freer's pediatric clinic has published several cases of poisoning by this drug which go to show that the book doses may be too high. The author reports three cases in great detail. Two patients were in the third and the other in the eighth year. In two cases the oil was apparently given only because of suspicion of worms, while in the other round worms had been found in the stools. The author concludes as follows: for both ascarides and oxyuris the oil of chenopodium is by far the best anthelmintic, but the book dose is too high. The right posology is about as follows: one drop for each year of the child's age should first be given; this should be repeated in an hour. Then after another two hours a large dose of some laxative should be given, and, should not stool appear after a second two-hour pause, the laxative must be repeated. A cure without severe purgation seems dubious. The symptoms of intoxication are drowsiness passing into somnolence and coma, unilateral clonic spasms and facial paresis, screaming, sluggish pupil reaction, horizontal nystagmus, abolished reflexes, and, exceptionally, death from respiratory paralysis.

News of the Week.

New York Charities Conference.—The New York City Conference of Charities and Corrections held its tenth annual meeting May 13, 14 and 15 for the purpose of discussing questions relative to public health, war labor problems, and public charities. Among those who contributed to the program were: Dr. Royal S. Copeland who spoke on public health problems; Justice Cornelius F. Collins of the Court of Special Sessions, on "After the Saloon, What?" Dr. Pearce Bailey, President of the New York State Commission for the Feebleminded, on "The Problem of the Feeble Minded in New York." Justice Collins expressed the opinion that an increased indulgence in habit forming drugs was almost certain to follow after prohibition and that legislation should be such as to permit medical judgment in prescribing alcohol. Dr. Walter H. Conley, acting General Medical Superintendent, Blackwell's Island Department of Charities and Correction, spoke on "The Unification and Control of Public Hospitals." He believed that an ideal form of control of public hospitals could be obtained by establishing a department of hospitals under the jurisdiction and direction of a commissioner. Under the present system the control of the city hospitals is under the jurisdiction of three different departments having similar plants and equipment and caring for the same cases, a condition of affairs leading to constant friction among employees, overlapping of work and economic waste. Dr. Charles H. John-

son, Secretary of the State Board of Charities, delivered an address on "Cooperation and Relation of Public and Private Agencies."

Boom in Insurance Follows Influenza.—Life insurance written by the companies operating in New York during the four months of 1919 has almost doubled over that of last year. Insurance company officials ascribe the remarkable increase to general prosperity, the lesson of Government war insurance of soldiers and sailors, and the influenza epidemic. Those who have studied the effect of the influenza epidemic mortality on insurance state that new life insurance increased with the rise of influenza mortality, and has continued to increase steadily until it has now soared to a point unprecedented in insurance history. The insurance companies were prepared to face a decrease in new business owing to the war, the fewer solicitors, and other causes; instead of a decrease the total business for the year if continued at the present level would be $10,000,000,000 as compared to $5,800,000,000 in 1918.

Gift to Mount Sinai Hospital.—The Mt. Sinai Hospital, New York, has received a gift of $150,000 from Mr. and Mrs. George Blumenthal for the erection of an auditorium building on the hospital grounds at Ninety-ninth Street and Fifth Avenue. Besides a large auditorium which will be devoted to the educational work of the hospital, the Mount Sinai Training School for Nurses, and the social service department, the new building will house an up-to-date *x*-ray department. The building is to be known as the Blumenthal Auditorium, and is to be erected as a memorial to George Blumenthal, Jr. It will be the sixteenth building in the Mount Sinai group.

Industrial Accidents in New Jersey.—Reports of industrial accidents made to the Department of Labor show a total of 16 fatal and 4916 non-fatal accidents last month. Of this total, nine fatal and 1336 non-fatal accidents are charged to factories and workshops.

Vanderbilt University Raided.—Police raided the medical laboratory of Vanderbilt University on May 12 and seized two patrol wagon loads of whiskey and other intoxicants. Four students were arrested charged with violating the State storage act.

Christian Science Healing Inquiry.—Recently the eight-year-old daughter of Andrew Walker of Newark died after having been under the care of a Christian Science healer for a week. The County Physician testified at the hearing that the child died as the result of diphtheria which could have been detected readily from the symptoms originally exhibited by the child. The law in New Jersey is that "the parents of a child or any person upon whom the duty is imposed to care for a weaker person, owe it to that person to care for and protect him, to provide proper medical attendance, and if, as a result of gross neglect, evincing a reckless disregard of human life, the child dies, the parent is guilty of manslaughter.

Dr. N. B. Potter's Memorial Laboratory and Clinic.—This institution, which was removed from the City Hospital, New York, to the Cottage Hospital, Santa Barbara, Cal., was formally dedicated at the Hotel Belvidere, on the eve of the annual meeting of the California State Medical Society, May 1. The new wing of the Cottage Hospital which houses the Memorial Laboratory and Clinic was made possible through the generosity of Mr. Billings, Mr. Knapp, and Mr. Peabody of Santa Barbara. The purpose of the Memorial Laboratory and Clinic is the study and treatment of nephritis, gout, and diabetes, under conditions which will provide for a thorough clinical and laboratory study of these diseases. The new building is being rapidly furnished and will be ready for occupancy within a fortnight. It is equipped with the latest type of electrocardiograph, a hydrotherapeutic establishment, a complete modern diet kitchen, chemical, biochemical, bacteriological, and clinical pathological laboratories. Some of the ward beds have been endowed so that they may now be offered to deserving sick poor residing outside of Santa Barbara. Dedicatory addresses were made by Dr. Chatfield Taylor and Dr. H. C. Moffitt who paid high tribute to Dr. Nathaniel Bowditch Potter, the Director of the institution, for his untiring zeal and enthusiasm in organizing the work.

Urge Opposition to Compulsory Health Insurance.—The Physicians' Protective League of New York, at its meeting on May 8, passed resolutions endorsing the action of the Medical Society of the State of New York in instructing its delegates to oppose Compulsory Health Insurance at the annual meeting of the American Medical Association and recommended similar action by other medical bodies in this State.

General Pershing Praises Nurses.—In a cablegram received at the headquarters of the American Red Cross in Washington, on May 13, General Pershing expressed the gratitude of the American troops in France for the devoted service of the army nurses enrolled through the American Red Cross. The letter says "The successful organization by the Red Cross of our nursing forces for war can hardly be overestimated. All of us in the American Expeditionary Forces have only gratitude for these devoted women who cared for our comrades and brought many back to life and health. To the late Miss Delano, Director of the Department of Nursing of the American Red Cross, we owe a special debt of thanks and admiration."

New League of Red Cross Societies.—A message from Paris announces the success of the Red Cross leaders in their efforts to unify and coördinate the Red Cross organizations in the United States, Great Britain, France, Italy, and Japan into a league of Red Cross Societies. The league which has been created will extend to Red Cross societies throughout the world and it is hoped through this plan of cooperation the Red Cross will become that great agency for the people's welfare which its founders determined it should be.

Treasury Gets Brooklyn Hospital.—The Norwegian Hospital at Fourth Avenue and Forty-sixth Street, Brooklyn, has been taken over by the Treasury Department. Last December it was taken by the War Department as a Base Hospital for wounded soldiers. The Treasury Department has taken the institution for the use of men cov-

ered by the War Insurance Act, whom the Army refuse to discharge from the service until cured.

Discussion on Thoracic Drainage.—In the very interesting discussion on this subject appearing in the report of the American Association for Thoracic Surgery in the issue of MEDICAL RECORD of May 10, the remarks of Dr. Willy Meyer were for spatial reasons published in the form of an original article. As Dr. Meyer had another article in the same issue we think it due him to state that this arrangement was made by the editor with the consent but not at the suggestion of the author.

Public Health Issue in Alabama.—Following a charge at the recent meeting of the Alabama Medical Society at Mobile that the State system of public health administration is grossly undemocratic as now constituted, a strong demand has developed for the enactment of laws at the session of the Legislature which meets in July to provide specifically that the public health administration shall be responsible to the people of Alabama. At the present time the Alabama Medical Society is constituted by law the State Board of Health. This society with a membership of 1800 appoints directly or through its subordinates every health official connected with the State Department of Health. It is now contended that laws should be enacted making the State Department of Health an integral and unquestioned part of State government, and consequently responsible to the wishes of the people. The State can through the Governor or otherwise call to account any official in other departments of the government. In the Health Department this is not possible since the Supreme Court has ruled that officials elected by the boards of health are mere agents of the boards, are not State officers and are not of or under the State.

Doctors Raise Fees.—The physicians of Chicopee, Mass., have voted to increase their fees. Under the new schedule which has already become effective, the fee for office calls remains at $1.00, while the house call fee is raised from $1.50 to $2.00. A fee of $1.00 is to be called for office telephone calls—which hitherto have been free. The night call fee has been raised from $2.00 to $3.00. A fee of $1.00 to $1.50 is charged for surgical dressings in the office and for outside surgical dressings, $2.00 to $2.50. Fees for industrial accident cases are to be from $3.00 up. The fee for confinements has been increased from $20 to $25.

The American Association for Thoracic Surgery will hold its annual meeting at Atlantic City on June 9. Further information regarding the meeting can be obtained by addressing the secretary, Dr. Nathan W. Green, 152 West Fifty-seventh Street, New York City.

The New York City Mortality Rate Drops.—The New York City Health Department calls attention to a noteworthy decrease in the mortality figures and the lessened prevalence of some diseases. The general death rate for the week of May 10 was well below that of the corresponding week of 1918, the rate being 12.16 per 1000 population for 1919 as against 14.19 in 1918. There was a decrease in the mortality from tuberculosis from 207 deaths for the week of May 10, 1918, to 160 deaths for the corresponding week of this year. Deaths from influenza and pneumonia combined amounted for this week to 247, as compared with 255 for the corresponding week of 1918. The records show that measles and whooping cough are less prevalent than usual.

The American Therapeutic Society will hold its annual meeting at Atlantic City on June 6 and 7. A program of the proceedings may be obtained from the secretary, Dr. Jacob Diner, 316 West Eighty-fourth Street, New York City.

The American Library Association will hold its 21st annual meeting at Atlantic City just preceding the meeting of the American Medical Association. The opening session will begin at 3 p. m., June 9, at the Hotel Marlborough. The Secretary of the Association is Dr. John Ruhräh, 1211 Cathedral Street, Baltimore, Md.

The American Association of Orificial Surgeons will hold its 32nd annual convention September 15, 16, and 17, at the Congress Hotel, Chicago. In addition to the usual scientific addresses and essays an extensive clinical program will be provided. Dr. Paul C. Goodlove, 504-5 Broadway Central Building, Detroit, Mich., is the secretary.

Commission for the Rehabilitation of the Industrially Crippled.—A Commission has recently been created by act of the New Jersey Legislature which provides for the rehabilitation of those crippled in industry. New Jersey is thus the first State in the Union to apply to her civilian population some of the lessons learned in the war. Governor Edge and the Commision recently visited United States Army General Hospital No. 3 at Colonia, N. J., for the purpose of investigating the methods of organized surgical reconstruction in operation there which might be applied with equal success in the case of the industrially crippled, and were so greatly impressed with the work that they appointed Dr. Fred H. Albee of New York, Chief of the Surgical Service in that hospital, Chairman of the Commission.

Colonel Depage Announces Plans for Edith Cavell Hospital.—Colonel Antoine Depage, professor of surgery at the University of Brussels and head of the Belgian Red Cross, has arrived in this country and intends to make a tour of the principal cities of the East to thank the people who contributed through his wife to the Belgian Relief Fund. In his first address in New York, on May 12, he announced his plan for building a memorial hospital at Brussels to bear the names of Edith Cavell and his wife, Marie Depage, who was one of the victims of the *Lusitania* disaster, drowned while returning with the funds collected in this country. Colonel Depage states that Mr. Lloyd George has started a fund in England to defray half of the expense of the institution.

Decorations for Women Workers in Luzancy Hospital.—The French Government has decorated twenty-two women who served during the war as physicians, surgeons, dentists, nurses, and ambulance drivers in conection with the American Women's Hospitals at Luzancy. Among the physicians and surgeons so honored are Dr. Delan Kinney of New York City, Dr. Louise Hurrell of Rochester, Dr. Charlotte Fairbanks of St. Johns-

bury, Vt., Dr. Kate Doherty of Milwaukee, Dr. Margaret Ethel Frazer of Denver, Dr. Mary MacLachlan of Portland, Ore., Dr. I. J. Manwaring of Norwich, Conn., Dr. Inez C. Bentley of Kings Park, L. I., Dr. Olga Stastney of Omaha, and Dr. Edna Ward of Littleton, Col.

Dr. H. H. Judd of Bozeman, has been appointed full time health officer of Gallatin County, Montana.

Major Alfred E. Lemon of Sault Ste. Marie, Mich., Surgeon of the 125th Infantry, who recently returned to this country has been decorated with the French Croix de Guerre, with a gold star, for bravery in action.

Charitable Bequests.—By the will of the late Bertha Herzfeld of Philadelphia the sum of $5,000 is bequeathed to the Jewish Hospital Association.

By the will of the late Thomas Skelton Harrison, of Philadelphia, bequests are made as follows: To the College of Physicians of Philadelphia, a portrait of Dr. Michael Leib, one of the founders of the College; Pennsylvania Hospital, $10,000; Day-Kimball Hospital of Putnam, Conn., $10,000, for the maintenance of Louise Harrison Beds; Philadelphia Home for Incurables, $5,000; Children's Hospital of Philadelphia, $4,000; Maternity Hospital, $5,000.

By the will of the late Mary E. Stuart of Philadelphia the following bequests are made: Presbyterian Hospital $5,000 for the maintenance of a free bed; American Oncologic Hospital $5,000 for study of the treatment of cancer; Philadelphia Home for Incurables $5,000; Rush Hospital for Consumption and Allied Diseases $2,500; Free Hospital for Consumptives $2,500.

Obituary Notes.—Dr. FOSTER SUDLER, a graduate of the Medical Department of the University of Pennsylvania, in 1896, died from tuberculosis at his home in Sudlersville, on May 8, aged 49 years.

Dr. JOSEPH W. MCKEE, a graduate of the Northwestern University Medical School in 1884, died from pneumonia at his home in Kansas City, Mo., on April 27, aged 69 years.

Dr. WILLIAM L. CAMPBELL, a graduate of the Kansas City Medical College in 1897, died from Bright's disease at his home in Kansas City, Mo., on April 24, aged 74 years.

Dr. FREDERIC RUSSELL STURGIS, a graduate of the Harvard Medical School, in 1867, died at his home in Boston on May 6, aged 75 years. He was formerly visiting physician to the City Hospital in New York City and a member of the Faculty of New York University from 1880 to 1882. He retired from the practice of medicine some years ago.

Dr. JOHN W. HOBART, a graduate of the Boston University School of Medicine, died suddenly at his home in Richmond, Virginia, on May 3, aged 80 years.

Dr. JAMES W. SNOWBALL, a graduate of Jefferson Medical College, in 1894, died at his home in Atlantic City on May 14, aged 55 years.

Dr. WILLIAM BEAM, formerly of Philadelphia, died at Khartoum, Africa, on April 15. He was a graduate of Jefferson Medical College. He had been for fifteen years in the employ of the British Government, in the capacity of chief chemist to the Wellcome Research Laboratories at Gordon Memorial College, Khartoum.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, April 23, 1919.

The Return of Rabies.—The occurrence of canine rabies in various parts of the country, but especially in and near London, has certainly had a disturbing effect upon the population, with whom the idea of there being any risk from hydrophobia has appeared a myth for the last twenty years. It is now more than twenty years since the incidence of rabies in various parts of the United Kingdom caused the authorities to take a strong line both as to the admission of animals from abroad and as to the muzzling of dogs at home. In those days the public did not receive the muzzling orders, which were issued by Mr. Walter Long as president of the Board of Agriculture, in any docile spirit, largely because the enemies of medical research were loud in their protests either that danger from rabies existed only in the minds of vivisectionists, or that, rabies or no rabies, man had no conceivable right to inconvenience his four-footed friend by putting a wire over his jaws. It happened, however, that Mr. Long, a strong and popular man, a sportsman who could not be suspected of faddism, and an old parliamentary hand, was very determined that the muzzling orders introduced by him should be stringently carried out. The good sense of the country backed him up with the result that whereas in 1895 there were 672 cases of hydrophobia reported in Great Britain, by 1903 the disease was extinct.

From that time forward no case of rabies occurred in the British Isles until September, 1918, when cases were reported simultaneously from Devonshire in the neighborhood of Plymouth and from the Isle of Man, which, of course, is in close connection with Portsmouth and Southampton. The actual number of cases which occurred is somewhat in doubt; but although no fatalities were reported, a large number of inoculations were carried out. I sent you a short account of this little epidemic at the time (see MEDICAL RECORD, October 19, 1918). The British Government made arrangements by which a center for antirabic treatment was established at Plymouth, so as to obviate the transport of all cases to the Pasteur Institute in Paris, and it was believed that the danger was over. Last week, however, cases were reported from one or two directions, notably, two in and near the neighborhood of London, with the result that a strict Muzzling Order has now been enjoined upon the Home Counties, and this may be a preliminary to a general Muzzling Order. A new arrangement has at the same time been made by the Local Government Board, which will enable antirabic treatment to be given in London as well as in Plymouth. The treatment will be given at the Pathological Department of St. Thomas's Hospital, Lambeth, by Colonel Leonard S. Dudgeon, who has received antirabic material prepared at the Pasteur Institute.

The Lancet reports that a regular system of interchange of information has now been established between the medical officers of the Local Government Board, the Department concerned with the

provision of antirabic treatment, and the Board of Agriculture, which is responsible for dealing with all questions relating to rabies in the dog. When, owing to close relation between the two departments, cases are early recognised and promptly treated, the danger should be over; but undoubtedly the outbreak has given considerable reason for wondering whether there are not a certain number of people who place their love of dogs far above their love of their fellow men. It is undoubted that these cases of rabies have their origin in the transport to England from France of infected dogs. There has been considerable canine infection for the last two or three years in France, and there seems no doubt that the English cases have been due to smuggling through quarantine of pet animals which have become infected.

War Neuroses and Psychical Treatment.—The discussion on war neuroses at the special clinical meeting of the British Medical Association, while a valuable one in many ways, was a little remarkable for the absence of all responsible communications concerning the psychical treatment of the condition under consideration. The exponents of hypnotism, suggestion-therapy and psychoanalysis had either not been bidden to the meeting, or were determined to remain silent in an apparently unsympathetic *milieu*. For one reason or another the result was the same, and the impression was produced that the British neurologist has no use for psychical treatment, a very unfortunate impression at this juncture in the case of neurological patients, and one which it was most undesirable to have evidenced in front of a representative group of American workers. But the absence from the debates of any broad psychological outlook might have escaped attention had not it been for a speech by the secretary of the section, a distinguished worker at the National Hospital for Paralysis and Epilepsy, who denounced the possible bad features of psychical treatment when it is left in unscrupulous hands, as though psychoanalysis and hypnotism can only be administered by charlatans. If the idea was to check the activities of psychical treatment the move was a mistaken one—an actual stimulus has been supplied.

An Interesting Exhibition.—In spite of the short time which the manufacturers had at their disposal to select and arrange their material, those who supported the exhibition which accompanied the Special Clinical Meeting of the British Medical Association succeeded in presenting a well-planned collection. Just as the general design of the Special Clinical Meeting was to illustrate the advances made in medicine and surgery during the war, so the trade exhibition proposed to illustrate advances made in the manufacture of surgical instruments, hospital appliances, drug, special foods, etc., which owe their origin to war conditions.

The number of new splints and new bandages was infinite, as might have been expected, but what proved to be of real value was the large assortment of more important apparatus, such as beds, sofas, reclining chairs, hand-chairs, and stretchers. War injuries were the cause of many of these mechanical contrivances, with the result that a large assortment of really ingenious medical furniture has come on the market. In this country, until now, save at one or two very well equipped hospitals, if a surgical bed of a particular pattern was required it had to be specially constructed at considerable expense, time and labour. Now sad but valuable experience has shown that these kinds of appliance follow certain recognised types and a good many articles in accordance with these types are being made and will be ready for use when required. The boon to country practice will be very great.

In the drug section of the exhibition the message which most exhibitors sought to convey was that the manufacture would now be possible in this country and in the United States of all the various therapeutic remedies whose original home was Germany. Boots Pure Drug Company, for example, showed among their British-made chemicals nine substances available in medicine whose supply as far as England is concerned had always been obtained before the war from two or three great German houses. Exactly the same words might be used of the exhibit of Messrs. Burgoyne, Burbridge & Co., a number of whose preparations had not been made in this country previous to 1914. Two of the American firms, with a large array of exhibits, had evidently worked with the deliberate intent of attacking German monopoly. Messrs. Burroughs, Wellcome & Co. are manufacturing and stocking the organic arsenic derivatives used in the treatment of syphilis, before the war made entirely in Germany, while Messrs. Parke, Davis & Co. are specialising in many new glandular products, whose original home was the same enemy country. Therapeutic and pharmaceutical industry has of recent years been more highly developed in the United States than in Great Britain and the condition of the war, while benefiting the pharmacy of both countries will, probably, at first at any rate, have a more marked effect in England, where there is more leeway to make up.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

PARIS, April 12, 1919

Peace Work of the Red Cross.—A conference of the leading authorities in medicine, surgery, bacteriology, hygiene, and sociology met at Cannes, on April 1, to formulate a program of world-wide scope and destined to continue in time of peace, and with the necessary modifications, the work, magnificently humanitarian in purpose and practical in character, that has been accomplished by the various Red Cross organizations during the war.

There is no necessity to describe that work in detail. Its benefits are recognized by all, for they have not been confined solely to combatants. In only too many cases, the sufferings of the civilian population of the battle-swept area would have been immeasurably greater but for the energy, initiative, and self-abnegation of Red Cross workers. In this extension of war relief work, the American Red Cross organization has been the pioneer and has achieved notable results. Under the vigilant and enlightened guidance of Mr. Henry P. Davison, formerly chairman of the War Council of the American Red Cross, now chairman of the Committee of Red Cross Societies,

its services have brought aid and comfort not only to the wounded and sick of the Allied Armies, French, British, Italian, Serbian, American, but also to destitute and suffering civilians.

The purpose of the conference at Cannes is to outline measures necessary to widen still further the field of activity of the Red Cross societies in time of peace, the first step in that direction being the organization of an International Council and Bureau of Hygiene and Public Health which will map out the work to be undertaken in the new war that is just opening, a war against disease. Although the organizations will, it is to be presumed, retain their national character, they are to combine and form what may be called a universal Red Cross Society with its activities coordinated under a central commitee of direction. The importance of this initiative cannot be over estimated. One of the underlying causes of the discontent now prevailing in so many parts of the world is the distress and disease that have been engendered by the war. What the League of Nations may perhaps be in maintaining peace, this union of Red Cross societies aims to be in protecting public health. It places child welfare in the forefront of its aims, and rightly, for unless infancy be safeguarded it is a never-ending task to create satisfactory social conditions. All humanity has a direct interest in the great project which the Red Cross societies, on the initiative of the American organization, are preparing to carry out; its progress will be followed everywhere with sympathetic attention and its success will be hailed with universal thanksgiving.

Lectures on Medical Progress.—At the request of the American Army Medical Corps, the professors of the Paris Faculty of Medicine will give a series of lectures on the progress realized in medicine by French professors. The lectures, which will be public, will be held every Tuesday and Friday at 4 P. M. in the large amphitheater of the Faculté de Médecine. The first lectures, fixed for the 25th and 28th of April, will be given by Professor Ch. Richet, who will speak of the work of Descartes, Lavoisier, Claude Bernard, and Pasteur.

Need of a Health Clause in the League of Nations.—Assuming that the League of Nations will be accepted by the different nations, then the necessity will soon arise for such a League to exercise certain clearly defined functions, which are today associated with every well-organized State. Such functions will be of an International character and will be exercised by the League by virtue of its being of the nature of a super-State. These functions are legislative, judicial, and administrative. Their nature and scope are or will be defined in the League Covenant. Labor and industry also are provided for by proper texts. But what about health? The vital subject that concerns each nation and every individual in it will surely have to be considered. If it is not dealt with in the original draft, it will have to be taken up as a subsequent amendment, involving naturally great delay. This is certainly the most opportune time to consider two of the great issues directly concerning all of mankind—the preservation of health and the prevention of disease.

The time is quite ripe that the question of sanitation and hygiene, both physical and mental, be taken care of, and it has been suggested that the Peace Conference create through the League of Nations an International Bureau similar to the proposed Bureau of Labor. For this purpose an article somewhat similar to the following one could be inserted in the permanent draft of the League of Nations: "The high contracting parties will endeavor to secure and maintain sanitary and hygienic conditions of living for men, women and children, both in their own countries and in all countries to which their commercial and industrial relations extend, and to that end agree to establish as part of the organization of the League a permanent International Bureau of Health."

A health crusade could be started to establish a standard for decent homes to live in and for safeguards of health throughout the world. Such a crusade, if properly conducted by a competent International Health Board, would bring about most beneficial and lasting results. The need will then arise for efficient health organizations in each country. Some countries are fortunate enough to have such health organizations at the present time, others are not. The simple reason for it is that competent local or national health boards depend for their efficiency mainly upon the individual health officers and sanitary engineers, who make up the health organizations in the smaller and larger communities.

Realizing the great need at the present time of such men and women, who would be competent in health matters, I strongly urged in a letter published in the New York *Herald* on January 8, 1919, the establishment by the American people of a large International Institute for Hygiene, Sanitation, and Sanitary Engineering in Paris as a "Victory Memorial" to commemorate the aid brought by the United States to the Allied cause in this war.

Such an institute would turn out efficient health officers and sanitary engineers, who could then go forth into their own communities and put into practice the best and most modern ideas in sanitation and hygiene.

146, Avenue des Champs Elysées.

LETTER FROM GENEVA.

(From Our Own Correspondent.)

Geneva, May 1, 1919.

Blood Changes Induced by a Milk Diet.—Some researches, which have not been published in the medical press, on the influence of an absolute milk diet on the blood in cases of acute nephritis have been carried out at the Laboratory of the Bordeaux Clinics by Lesson. He admits, naturally, that the blood changes noted at the onset of a nephritis, before a milk diet or other treatment has been begun, viz., a decrease in the number of red blood corpuscles and percentage of hemoglobin, a slight leucocytosis, an intense neutrophile polynucleosis and a considerable decrease in the number of lymphocytes, are due to the morbid process itself. During the evolution of an acute nephritis Lesson found that when the albu-

minuria persisted there was a more marked decrease of hemoglobin, a more intense leucocytosis, a still more accentuated diminution of the lymphocytes than at the onset of the renal process, while the number of red blood corpuscles and the proportion of polynuclear neutrophile leucocytes remained about stationary in percentage, the first greatly below, the second very much above, the normal.

On the other hand, Lesson found that an absolute milk diet for one week in a healthy subject did not cause any notable change in the percentage of hemoglobin or in the number of red blood corpuscles, but that it did produce a marked leucocytosis characterized during the first six days by a lymphocytosis and on the seventh and eighth day by a rather high neutrophile polynucleosis combined with a marked diminution of the lymphocytes. This latter hematological change coincided with a state of fatigue and asthenia of extreme degree.

But the anemic condition noted immediately after cessation of the milk diet, and which continued to increase for still another week, has led Lesson to conclude that, in all probability, had the milk diet been continued for a longer period of time the phenomena of anemia would have become manifest during this diet. Therefore, it would seem only logical to admit that in acute nephritis the fall in the red blood corpuscle count and percentage of hemoglobin and lymphocytes on the one hand, and on the other the increase in the number of white cells and proportion of the polynuclear neutrophile leucocytes should be attributed in part to the milk diet and in part to the renal process.

But the changes noted in the blood of patients with acute nephritis while still on an exclusive milk diet, although the albuminuria had disappeared, only partially corroborate this conclusion. In point of fact, at this time the hemoglobin and red blood corpuscles, although being below normal, had a tendency to increase, while the leucocytosis which was still notable, tended to diminish. On this point Lesson's conclusion seems to be confirmed, viz., that one of the factors to which he attributed the blood changes due to acute nephritis having disappeared, these changes must evidently be less.

On the other hand, he noted at the same time that the percentage of polynuclear neutrophile leucocytes and lymphocytes returned within nearly normal limits, and although, perhaps, this phenomenon may be exceptional, Lesson is of the opinion that much reserve is to be maintained on this point until the contrary is proved. He consequently concludes that if, during the evolution of an acute nephritis, during an absolute milk diet of three weeks' to one month's duration, the increase in the number of white cells is more marked than at the onset of the renal process, the explanation is to be found in the fact that the milk diet has added its action to that of the nephritis and thus has contributed its share to this blood change.

Treatment of Graves' Disease.—Dr. G. Masson, working at the University of Geneva on the subject of exophthalmic goiter, has formulated the following conclusions in his recent thesis (Dec. 4, 1918). The disturbance of the thyroid secretion (dysthyroidia) appears to be alone the cause of the production of the symptoms of this affection. The dysthyroid theory is based on clinical data, as well as on experimental, pathological, and therapeutic facts.

The treatment with sera obtained from thyroidectomized animals is that which gives the best results, and this treatment is at the same time logical, but it must be continued for a long period of time. It gives rapid results, but if interrupted the symptoms quickly return. It does not, however, appear to bring about a complete and permanent cure, although so long as it is continued, it assures a functional cure which is often perfect. The lacteal treatment by milk from a thyroidectomized goat gives far better results than any other form of antithyroid treatment. The subjective state of the patient is particularly favorably influenced. The dose of the milk should be from ¾ to 2 liters daily, and it also appears that radiotherapy can be combined with advantage. This treatment is perfectly logical, since it aims at the functional suppression of the pathological gland, while antithyroid treatment neutralizes the toxic secretion only. Surgical treatment should be reserved for those cases in which medical treatment has failed or where the gravity of the condition necessitates urgent action.

Unrepentant Teutons.—The desire proclaimed by Herr Theodore Wolff and publicly professed by other leading men of Germany that the errors of the past should be duly inquired into and the responsibilities not only for the outbreak of the war, but for such misdeeds as the sinking of the *Lusitania*, the ordering of the ruthless submarine campaign, and the deporting of peaceful civilians should be fixed once for all, does not seem so far to have produced much sincere searching of the national conscience.

A specially called meeting of the Berliner medizinische Gesellschaft was held a few weeks ago to consider the possibility of renewing scientific relations—"exchange of scientific thought"—with the learned of the enemy nations. The French Academy of Science and the Surgical Society of Belgium have declared that no such relations could possibly be entertained with any German man of science who had not first publicly declared his disapproval and condemnation of the deeds of which the military authorities had been guilty. A member of the Gesellschaft proposed that the medical body should spontaneously make this declaration. The proposal was negatived, and the matter was referred to a special commission, which reported against any such step. It declared that, although much might be said on the subject, the French military authorities had been equally guilty of inhumane proceedings against German prisoners. After much discussion the society came to the conclusion to take no decision until French medical men consented to examine French misdeeds in the same spirit and took the first step. So there is an end to future exchange of scientific thought with Germany of the present generation, at least so far as the medical body is concerned.

4. What Is Neuritis and How Should It Be Treated?—William Martin discusses the term neuritis as it is understood by various authorities and points out that it is not safe to depend upon atrophy in reaching a diagnosis, as this symptom may take place after a few weeks of involvement or may not appear for years. In terminal cases where the reaction of degeneration is present or atrophy so evident that it cannot be mistaken, differential diagnosis can usually be made by means of the *x*-ray and this method is particularly applicable in cases of bursitis where diagnosis is not otherwise possible, and in cases of sacroiliac relaxation and arthritis where the symptoms are so nearly alike. The static machine plays an active part in the diagnosis of neuritis and the writer, believing that many physicians know little or nothing about this apparatus and its use, goes into the matter in detail. The patient is seated upon an insulated platform and he is connected with the apparatus by a wire attached to a flexible metal electrode. This may be of any size selected by the operator, but the usual one is approximately 2 by 4 in. This is placed over the area that is thought to be involved, and the machine started with the poles together, the wire attached to the positive side and the negative grounded. As the poles are separated the current jumps across the spark gap, causing interruptions, which are carried to the patient under the electrode. These interruptions cause alternate contractions and relaxations, and are mechanical in nature. If the nerve under the electrode is at all inflamed the amount of pain produced will be in proportion to the length of the spark. If there is no nerve inflammation there will be no painful response, but merely a contraction effect of the part. This is a positive test of whether there is such a condition present or not, and should always be tried whenever possible. There are cases in which there are areas of pain in parts of the body other than where one would expect to find them; there may be pain in the ball of the foot, due to a sciatic neuritis. Such cases should have the test made over the course of the nerve supplying the part. In case of foot pain the sciatic nerve should be tested, and it will generally respond. Since the pathology of neuritis is the same as that of any other inflammatory condition, accompanied by an exudate, treatment must be directed to the exudate as well as to the muscular spasm. The quantity of the exudate varies with the duration of the condition and in long-standing cases may form adhesions involving the muscular structures; *e.g.* the difficulty of raising the arm in a brachial neuritis. Without treatment, such cases gradually become worse and end in atrophy, and therefore, prompt relief is of the utmost importance. In order to give prompt relief a mechanical method is absolutely necessary and in the static current we have the practical and only means of cure. The author points out that in an acute neuritis in a nervous woman it is better to start with a soothing application, such as radiant light and heat, given by a properly hooded high candle-powered carbon filament lamp, which should be used to the point of producing active hyperemia. Following this, the high frequency current may be applied by the diathermic method to great advantage and without causing pain. The d'Arsonval current is used for this, and is applied by the use of two electrodes of metal of suitable size, properly placed; that is, one over the painful area and the other on a part of the body opposing it, so that the current may pass directly through and heat the tissues to a certain degree, which must be determined for each case. After some days of this treatment the soreness will be greatly diminished and treatment is then given by the static current as already described, the time application being extended according to the requirements of the particular case. As the treatment advances the strength of the current may be increased, as more current can be used without causing pain; this indicates that progress is being made towards a cure. When the wave current is ended, it is usually followed by indirect sparks. These are short, sharp applications made by the use of a special applicator directly to the area involved, and guided by a special electrode. The results are quick, sharp contractions which aid materially in breaking down adhesions. The method of applying these indirect sparks is as follows: The patient remains upon an insulated stand, which is connected with a metal crook or rod to the positive side of the machine, the negative is grounded as with the wave current, but with both poles wide apart. The operator holds the sparking electrode, which is grounded with a second ground chain attached to the water system or a gas pipe, and not to the apparatus. The machine is started slowly, and as the sparking electrode is applied near the surface, a spark jumps across the intervening distance, which produces a profound contraction of the tissues under treatment. The strength of the spark can be modified by decreasing the speed of the machine, or placing the operator's foot upon the insulated stand. In sparking around small joints, such as the knuckles, a spark director held against the part will give the best satisfaction. Martin states that the majority of cases will be amenable to the methods of treatment outlined. The ionic method, however, is also recognized as of great value, particularly in cases associated with arthritis. The practical application of these methods requires a fair knowledge of their physics. Electricity cannot be used empirically if results are desired and, for this reason, this branch of therapy should receive just recognition and be properly taught in all medical colleges.

2. Stone in the Common Duct: With Analysis of Fifty Cases.—A. Murat Willis draws attention to the following facts: (1) Stones are present in the common duct in a considerable number of patients suffering from cholelithiasis; in approximately 10 per cent. of the author's cases. (2) A certain number of patients with stone in the common duct do not present symptoms sufficiently suggestive to justify exploration of the duct, and in some of these cases, palpation will fail to disclose the presence of the stone. (3) Even exploration of the duct sometimes fails to reveal the presence of calculi, though the previous and subsequent history of these patients may indicate or prove that stones were actually present. Willis points out that the mortality in common duct cases subjected to operation is variously given at from 6 to 16 per cent. In his series, five patients died, giving a mortality of 10 per cent. In gallbladder cases, exclusive of those showing calculi in the common duct, the mortality was 2 per cent. From these figures it is evident that in cholelithiasis cases operation should be performed before the entrance or formation of the calculus in the common duct. The condition is essentially a surgical problem and medical temporizing is fraught with peril

to the patient. The author gives the history of five fatal cases, from which it is seen that hemorrhage was the striking feature of all. Bleeding was the direct or strongly contributory cause of death in every instance. The most rapidly fatal hemorrhage occurred in those patients in whom, for some cause, an acute exacerbation was superimposed on a chronic jaundice. Although delay and expectant treatment are indicated in some types of abdominal infection, the author believes that this rule cannot be followed in cases of infection with obstruction of the common duct. Acute jaundice is not so potent a factor in producing the hemorrhagic diathesis as chronic jaundice is and the author states that in future, in common duct cases, the appearance of jaundice will be an important factor in his decision for immediate operation.

4. Comparative Prognosis of Tuberculous Lesions of Right and Left Lung. Report of Five Hundred Cases.—Louis Mark states that during the routine examination of patients in the women's service at the Ohio State Sanatorium, he observed that cases with a greater amount of active involvement of the left lung progressed more slowly towards quiescence than those in which the right lung was more involved. Moreover, while doing a large number of necropsies on tuberculous subjects, he repeatedly noticed that in the majority of cases of bilateral tuberculosis the right lung showed considerable involvement at the apex, with a marked tendency towards fibrosis, whereas the left lung was usually heavily infiltrated from apex to base with a thickening of the pleura and very firm pleural adhesions but very little fibrosis of the lung. This seemed to show that the initial lesion had been in the right lung, but the left lung showed the greater amount of active involvement. He also found that in 75 per cent. of pneumothorax cases, the left lung was the one that had to be collapsed. In the far advanced cases discharged from the institution as too sick for the routine, the percentage of left-side cases was greater than of right. From this the author concludes that in this type of case, when the left lung shows the greater amount of involvement, the prognosis of building the person back to working capacity or of bringing the chest to at least a point of quiescence is far less favorable than in right lung cases. This is also true of incipient cases since those with left lung infection make much slower progress than the right-sided cases, though it may not be true to state that a left lung infection will not improve or become quiescent. Patients with left-side involvement, therefore, should be given a longer period of absolute bed care, and exercise, when begun, should be prescribed guardedly and increased slowly. A number of these patients may present a normal or a subnormal temperature with only a slight variation between morning and afternoon and a fairly constant pulse, but on physical examination will show little tendency towards fibrosis, and when exercise is prescribed may stand it very well for a while but will have a return of clinical symptoms (which is the first warning of a possible breakdown) much sooner than a patient with the same amount of involvement of the right lung. The author points out that there are several reasons which may account for the more rapid spread of a tuberculous focus in the left lung than in the right: the left lung is considerably smaller and has but two lobes; the bronchus leading to the left lung forms a more obtuse angle and is much smaller than the right bronchus; there are two fissures on the right and only one on the left. The interlobar clefts fence in the infection and prevent one lobe from becoming infected by the other except through the regular channels along the bronchial tree. This fencing by the interlobar pleura is repeatedly seen on roentgenograms of the chest and also in the sectioning of tuberculous lungs at necropsy. From his observations the author concludes that : (1) The amount of involvement being equal, the prognosis of lesions of the left lung is not as good as of the right. (2) Prognosis of the male cases is better than of the female cases. (3) There is less tendency toward fibrosis in the left than in the right lung. (4) Patients with active tuberculous lesions in the left lung require absolute bed care over a longer period of time than the right-side cases to produce the same results. (5) Rapid gain in weight, especially of the left side cases, does not always mean rapid progress toward quiescence. (6) Artificial pneumothorax of the left lung is more frequent than of the right. (7) The greater number of incipient cases show tuberculosis of the right lung, and the greater number of advanced cases in the left lung. The percentages of right and left lung cases are equal when all stages of the disease are considered.

4. Gas Gangrene Due to Infection with a New Pathogenic Anaerobe—the Bacillus Tumefaciens.—Brevet Major W. James Wilson reports a case of gas gangrene in which the subcutaneous injection of Weinberg's serum was without effect. At the time of operation 50 c.c. of this serum was given, the dose being made up of 20 c.c. antiperfringens, 10 c.c. antiedematiens, and 20 c.c. antivibrion septique sera; and on the following day 60 c.c. was given, the dose for antiperfringens being increased to 30 c.c. In spite of surgical and serum treatment, gangrene advanced and the patient died at 1 a.m. the next day. At postmortem patient presented a clinical picture of gas gangrene. The failure of the serum in this case was explained by the bacteriological fiindings; neither *B perfringens*, *B. œdematiens*, nor *Vibrion septique* were present in the lesions, but an organism which the author has named the *Bacillus tumefaciens* on account of the rapidity with which it produces a large edematous tumor or swelling, was recovered and proved to be pathogenic to rabbits and guinea pigs. One c.c. of a 48 hours' meat broth culture of this organism was injected subcutaneously and into the muscles of the right thigh of a guinea pig. The animal died within 24 hours. Postmortem examination revealed a large tumor in the right groin, the swelling consisting of a pink jelly-like mass of solid edema; the muscles underneath contained gas and showed hemorrhages. The abdominal wall was reddened both inside and out on the affected side. The *Bacillus tumefaciens* is an actively motile Gram-positive bacillus. In morphological characters it resembles the *Vibrion septique*, but it is easier to cultivate and forms spores, especially in carbohydrate media, with the utmost facility. Like the *Vibrion septique*, it often shows swollen citron forms, long threads, and "granulose" bodies. It is essentially a saccharolytic bacillus and fails to digest either coagulated egg albumen or serum. In litmus milk it produces acid and gas. Clotted casein is not digested and remains red in color—*i.e.* there is no bleaching. Spores were found in milk culture. The deep colonies in 0.1 per cent. glucose agar resemble those of the *Vibrion septique*. In fermenting saccharose, inulin, and glycerine it resembles some strains of *B. Welchii* and differs from *Vibrion septique*, but resembles the latter in fermenting salicin. It is far more active in its action on sugars than the two strains of *B. œdematiens* with which the author has compared it. In meat broth culture the fragments of muscle become pink in color and no digestion occurs. It hemolyses red blood cells. The author has compared this organism with the various bacteria described in war wounds by English, French, German and American bacteriologists and has come to the conclusion that it is a new species. Though it resembles Aschoff's "Gasoedembazillus," there are the following differences: *B. tumefaciens* is actively, the "Gasoedembazillus" feebly, motile; spores are more readily formed by the *B. tumefaciens* both in the animal body and in culture; lesions caused by the "Gasoedembazillus" are characterized by a clear, gelatinous edema, while those produced by the *B. tumefaciens* resemble those of the *Vibrion septique* in being hemorrhagic. The author adds that further study is required to determine the

position of this organism among the pathogenic anaerobes; in the meantime he believes himself to be justified in giving it the name of *Bacillus tumefaciens.*

2. War Headache and Its Surgical Treatment.—Major L. Bathe Rawling attempted surgical treatment of headache first in India, where many severe and persistent cases came under his care. The immediate improvement that followed decompression when all other measures had failed led him to adopt the same treatment with considerable confidence in cases of war headache, which were secondary to gunshot wounds, concussion, fractured base, etc. In the cases operated on in India a marked degree of cerebral edema was found, and in explanation of this the author adopts the hypothesis that, under abnormal conditions the absorptive capacity of the surface cerebral vessels is impaired and the cerebrospinal fluid, though secreted at a normal rate, is not absorbed in direct ratio; it, therefore, accumulates in the subarachnoid spaces, bogs the surface of the brain, and even forces its way into the adventitious subdural space. In regard to cases of war headache he points out that :(1) The more severe headaches are associated with an intact skull (closed box) or with small defects. With large deficiencies headaches are less frequent. (2) Frontal and temporal injuries are more commonly accompanied by headache than injuries in the parietal, occipital, and cerebellar regions. (3) Wounds near the vertex, in relation to the superior longitudinal sinus, are frequently associated with a severe type of headache. (4) The presence of foreign bodies within the skull is commonly accompanied by chronic headache, more especially when the foreign body is situated in relation to the ventricles of the brain. As a rule the headache dates from the moment of recovery of consciousness, either from the injury or from the operation carried out for the injury. The severity of the headache varies very greatly, the "cyclic" form being perhaps the most common, and a possible explanation of this is that the cerebrospinal fluid, by reason of insufficient absorption, slowly increases in quantity, finally arriving at a certain maximum, which coincides with the period of maximum intensity of headache; the increased intracranial pressure results in the opening of various channels by which some excess fluid escapes and relief takes place automatically. In other cases, the pains show little variation in degree, persisting both day and night without intermission. The author has had patients who have put up with this suffering since 1914 and have despaired of cure. Wherever the injury, these headaches tend to become localized to the frontal region, behind the eyes, perhaps more acute on the side injured. Sometimes there is a maximum "bursting" pain over the summit of the vertex, and sometimes the symptoms suggest a spreading cerebritis, ventriculitis, or meningitis. Any mental or bodily exertion, noises, joltings, and especially moving pictures will start these headaches, and they are particularly liable to come on upon awakening or in the evening. Among the symptoms associated with the headaches, the author mentions slowing of pulse rate, with little raising of blood pressure, giddiness, persistent elevation of temperature, insomnia, slow cerebration, anxiety and depression, exaggeration of all reflexes, slight blurring of discs and dimunition of visual fields, fits. Appetite is usually good and bowels natural, except for some constipation; urine is normal. In the majority of cases, Rawling attributes these headaches to cerebral edema. In some few cases, however, no edema has been found at operation—merely a tense dura mater and a brain under pressure. In such cases it would seem that there is a condition of ventricular distension, due probably to interference in the normal channels at the base of the brain, with perhaps some ventricular hypersecretion. In these latter cases true papilledema is more likely to be present and the patient evidences more marked apathy and somnolence. Operative measures are indicated in both conditions. Treatment, the author considers under three heads: Rest, with dietetics and drugs; lumbar puncture, and decompression. Treatment by rest, careful dieting and drugs, though carried out for three months, has proved of no avail, as the headaches have returned as soon as the patient got out of bed; lumbar puncture has also failed, both from the point of view of diagnosis and treatment—sometimes it has produced temporary relief, but in other cases it has been followed by an exacerbation of the pain. Subtemporal decompression, on the other hand, will almost certainly bring about relief or cure within forty-eight hours of the operation without in any way risking the patient's life and well-being. The author urges: (1) That all other measures be given free and fair trial, with a probationary period of about three months, unless urgency prevails; (2) That operation be reserved for the more acute cases, and for those more severe chronic cases where the patient is rendered miserable by reason of headache and associated incapacity; (3) That the operation should be so conducted as to provide adequate decompression effect, and that the trephining should be carried out under cover of the temporal muscle. There should be such removal of bone and such dural incision as shall allow of the escape into the temporal tissues of the excess cerebrospinal fluid, suflicing to lower adequately the intracranial pressure. The patient should be warned of the "new" pains which may develop as the immediate result of the operation, but which will subsequently disappear. The immediate effect of the operation is most marked; headache which may have existed for months or years as a rule completely disappears within twenty-four to forty-eight hours. During the next three weeks or so, the convalescing stage, mild recurrences of the "old" headache may take place, but they are readily controlled by aspirin. It is common, however, for the patient to complain of neuralgic pain in the temporal region, stiffness in the masticatory muscles, and a "thumping" pain in the immediate vicinity of the decompression opening for the few days after the operation. In a few cases where these "new" pains have been unusually severe, there has been some trouble at operation from bleeding, or patient has vomited after the operation. There has also been some tenseness in these cases over the decompression opening which may be due to an effusion of blood or the free escape of cerebrospinal fluid and a too slow absorption thereof. Within three weeks, however, both "new" and "old" pains should have disappeared. The late results have been equally encouraging and real relapse has been rare. A brief summary of twenty cases is appended.

6. A Note on the Variety and Latency of Organisms on Missiles in the Tissues.—Major F. C. Pybus, Capt. H. J. Slade, and P. W. C. Laws have conducted a systematic examination of forty-four specimen of missiles removed from the tissues with the usual surgical precautions and dropped into a sterile tube. The results of their examinations have led them to the following conclusions: (1) That most pyogenic organisms can persist in the tissues for periods up to at least thirty months. (2) That they may at any time give rise to inflammation, and that this is possible in at least 50 per cent. of cases. (3) That prophylactic measures before removal might be useful. (4) That if possible the missile be removed complete in its fibrous tissue capsule. (5) That if such be impossible, careful disinfection of the cavity be carried out.

Wiener medizinische Wochenschrift.

March 1, 1919.

Ozena.—L. Rethi states that the specificity of Perez's cocco-bacillus is rendered probable on account of its affinity for the nasal mucosa, proved by animal experimentation, as well as by the results obtained by vaccino-

therapy. The latter treatment, however, in no way lessens the therapeutic services offered by electrolysis.

The Working Capacity of Subjects with Internal Disease Due to Warfare.—I. Schütz points out that the estimate of working capacity is made by a progressive training of the subject during a stay in hospital and thus can be fixed the amount of work that he can furnish without injury to himself. In renal subjects, the repeated dosage of albumin and the variations in the blood-pressure are excellent guides as to the working tolerance of the subject.

La Presse Médicale.

April 7, 1919.

The Minor Symptoms of Aerophagy.—Leven states that air-swallowing does not receive the attention it merits from the profession, considering its significance in the causation of gastric, intestinal, cardiac, respiratory and other ailments. The principal symptoms of eructation may be inconspicuous or absent, and we often owe our first information as to the presence of the condition to the radioscope. But the author believes that the diagnosis can often be made by the minor signs. At his own hands he finds this means almost absolute for diagnosis. When a suspect presents himself at the clinic he first asks to see his tongue. The latter may be red, moist, and shining—typical for some forms of severe dyspepsia. The students whisper "what a fine tongue," for with them dyspeptics should have a gray, dirty-looking tongue. The author tells them it is a wretched tongue—it is too red, too shiny. It is bathed in saliva. Were it dry it would be a diabetic tongue, but being overmoist it is the tongue of an air-swallower. The normal tongue is very slightly gray or opaline, and just a trifle moist. Should such a patient develop air-swallowing, not only the tongue changes, as stated above, but the lips take on a similar appearance—of redness, moisture, and shining, due evidently to sialorrhea. To make sure that the latter is present, ask to see the patient's pillow or ask him if he drools in his sleep. This he will surely do. The sialorrhea leads to swallowing the saliva. Frequent swallowing causes an irritation in the region of the larynx and these patients, as a rule, find themselves unable to wear tight collars. A third type of symptom is inability to sleep on the left side—sleeping on the right side suggests the ærophage, but is by no means pathognomic. If he sleeps on the left side he suffers perhaps from palpitation, perhaps from false angina pectoris. In regard to belching, the patient oftentimes is aspirating more air when he believes himself forcing it out. This occurs especially when the patient during eructation bends forward his head and rests his chin on his chest. According to Soupault, this position means that air is swallowed and when present it is pathognomic. Mere belching is not indicative of ærophagy.

Hygiea.

February 28, 1919.

Case of Primary Pleural Sarcoma.—Roman relates the case of a man of twenty-two with left-sided malignant growth of the pleura with autopsy finds. The patient first suffered with ordinary pleuritis of exudative type, or, rather, the symptoms suggested that affection. There was a stabbing pain for several weeks immediately beneath the left nipple. At no time had there been any cough. On his first visit to the hospital he appeared to have an exudation in the left pleura of such extent that a thoracentesis was necessary to free the heart and other intrathoracic organs. The fluid was turbid and very bloody and the operation gave no relief. This fact, with absence of cough, led to a suspicion of neoplasm. The fluid quickly reassembled and a cachexia developed with progressive dyspnea, ending in death. The total absence of sputum and cough, and the absence of relief after tapping, led to an exploration of the pleural sac with a trochar, whereupon a firm, uneven mass could be mapped out. Autopsy revealed the presence of a primary pleural sarcoma. The microscopic examination after death showed the form to be a small round cell.

Boletin de la Asociacion Medica de Puerto Rico.

March, 1919.

Pappataci Fever in Puerto Rico.—Barriero informs the reader that this affection exists upon the Island (although we have never encountered the statement before that it occurs anywhere in the New World). It has been seen at least since 1912. There appears no reason why it should not extend to the United States. There has been a good opportunity to compare this malady with the recent outbreak of influenza, and the author institutes a parallel in which twenty-two symptoms are compared in each disease. He has probably drawn in part on the experience of Italy and other countries in which three-day fever occurs. The parallel is surprising and startling, for apparently there is almost no difference between papataci fever and mild influenza, while the totality of difference is essentially the much severer quality of grippe and the fact of sandfly transmission. A close analysis shows that in the sandfly fever bronchial symptoms are less pronounced and constant than in mild influenza, but to offset this fact we must not forget the extrathoracic type of grippe. The pharyngitis of three-day fever is said to be more severe than that of grippe, a statement which will not perhaps hold good save in mild cases of the latter. The ocular reaction and the skin reaction also seem more marked in three-day fever. In the latter the kidneys do not suffer, there is no complicating pneumonia, the patient has no marked prostration, does not look especially ill, and is never out of his head. But some of the symptoms hailed as absent from three-day fever are absent from mild and moderate influenza, and some present in three-day fever have been seen in old pandemics of influenza. Some curious parallelism is seen in the bradycardia present in both affections, in the second rise of temperature, etc. In many cases diagnosis is impossible between the two, from symptoms alone. The rapid diffusion, the grave type of case, the pneumonias, and insect transmission enable us to differentiate.

Il Policlinico.

March 9, 1919.

Streptococcus Pandemicus.—Segale, a director of military laboratories at Genoa, refers to the growing belief in the existence of a filtrable virus as the initial mischief-maker in pandemic grippe. This, in the light of laboratory and other experimental medicine, is sufficient to cause bronchopneumonia. The author has surveyed many experimental researches with virulent filtrates, and the weight of evidence is in favor of a belief in a filtrable virus. He himself has also been active in this field and recently isolated a streptococcus which passed through the filter, yet was active enough to cause a reaction in the nasal mucosæ after direct inoculation. This germ, named by the author *Streptococcus pandemicus*, after prolonged cultivation and filtration through a Chamberland filter, set up a respiratory syndrome in guinea-pigs with the following lesions: congestion, hyperemia, infarcts, ecchymoses, hemorrhages. In another pig there was evidence only of peribronchitis, while in a third case the result was negative. The author continues with an account of other experiments, from which it abundantly appears that at least in the guinea-pig this filtered germ can set up a series of intrathoracic and general phenomena which closely parallel those of grippe. The author now compares his own filtrable germ with those described by American and English authors and concludes that they are identical. He ignores or does not seem aware of other filtrable germs, also cocci, although a study of these might support his thesis.

Syphilis in the French Army.—Simon states that in 1916 there were 9,000 cases of syphilitic chancre in the army. To obtain the total one uses 5 as a multiplier and obtains the figure 45,000 for chancres alone, for the entire course of the war, which may be doubled to include cases which escaped recognition. This total is much less than the estimates of some syphilographers who make the number somewhere between 200,000 and 300,000. Those who were infected before the war are evidently not included.—*La Presse Médicale.*

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Thirteenth Annual Meeting, Held in Syracuse, May 6, 7, and 8, 1919.

(Special Report to the MEDICAL RECORD.)

(*Continued from page* 849.)

SECTION ON MEDICINE.

First Day—Tuesday, May 6.

THIS was a joint meeting with the Section on Eye, Ear, Nose and Throat.

Encephalitis Lethargica.—Dr. SIMON FLEXNER of New York presented this subject, in dealing with which he made a comparison of the differential points between this disease and poliomyelitis. The anatomical difference was noted; in poliomyelitis it was found that the spinal cord is most affected and sometimes areas in the medulla, but the higher centers of the mid-brain are little or not at all involved. It had been stated that in encephalitis lethargica the spinal cord escaped infection, but this, Dr. Flexner said, had not been his experience; he had noticed involvement of the spinal cord, which, he thought, brought the two diseases more closely together. On the other hand, the extent of involvement of the mid-brain in encephalitis lethargica was out of all proportion to that noted in poliomyelitis. The localization of the disease in certain regions was that which would best account for the symptoms most common in the disease. One early symptom is involvement of the third cranial nerve, with accompanying lesion of the optic thalamus, the origin and direction of which is closely associated with that of the cranial nerve, in such a degree that the affection of both was easily understood. Furthermore, the external stimuli that keep people awake pass through the optic thalamus on the way to the higher brain centers, thus, when this region was blocked it favored the development of stupor and the lethargic state. In regard to infection, poliomyelitis could be communicated to monkeys and induce in them the corresponding clinical signs and pathological lesions which are present in the human being. The speaker quoted one report which was made in Vienna, and was referred to in the French literature of successful communication of encephalitis to a monkey. However, from the description of the so-called "successful transmission" Dr. Flexner said he felt that no real transmission took place, that the material inoculated was not sterile and that the infection of the animal was of the streptococcus type. They had tried a small number of inoculations at the Rockefeller Institute but in no instance had they achieved unequivocal results. He could not say that no one would ever be able to do so, but never with the ease with which poliomyelitis could be induced in that animal. Another difference to be emphasized was that those individuals who had poliomyelitis and who died, died within the first few days, because of the involvement of the spinal cord and the overwhelming of the respiratory centers and death took place from asphyxiation. In encephalitis lethargica, on the other hand, there are few early deaths, but mostly after weeks or months, and the nervous involvement is progressive; a disphagia takes place and it is necessary to feed the patient by tube. A terminal bronchopneumonia usually supervenes. Attempts had been made to cause the disease in monkeys by using the nervous tissue of old cases, but this was difficult, and so materials had been tried of more recent origin, that is, from cases 8 or 9 days old. This was taken out with great precaution as to complete sterility, but thus far there were no successful results from the inoculation. Dr. Flexner then showed lantern slides illustrating the involvement of cellular tissue and of vascular changes in the brain; involvement of the spinal ganglia; of the lateral ventricle with complete wiping out of nervous structure; hemorrhages, both microscopical and macroscopical, the distribution of which differed much from those in poliomyelitis; infiltration of the pia. The question might be asked, Dr. Flexner said, as to how much influence was noted on the cerebrospinal fluid in encephalitis lethargica, that there were certainly increased cells and globulin but much less, however, than in meningitis or in poliomyelitis. There was no doubt that in this encephalitis lethargica there was a proven disease of the central nervous system. It could be considered as an infectious, communicable disease, but to what extent it had been transmitted would not be known until reports had been made and studied to determine which were really cases of the disease and which were not.

Dr. ISRAEL STRAUSS of New York said that Dr. Flexner had given an interesting presentation of the pathology of the lesion. The neurologists had a very definite clinical description of the disease and of its types. Dr. Flexner had dealt thoroughly with the question which had bothered neurologists and pathologists alike, the relation of this disease to poliomyelitis; some writers had even gone so far as to claim that the diseases were identical. Much experience had been gained in Dr. Sachs' wards at Mt. Sinai in which 40 cases of encephalitis lethargica had been studied. They had been able to exclude syphilis and other disease of the central nervous system by the study of the cerebrospinal fluids. In one early case 160 cells were counted, which was far less than one would find in poliomyelitis. Another feature was that in many of the cases there was a history of one, two or three months' previous influenza infection; one case ten days after influenza infection. The British workers, Dr. Strauss said, do not connect the two diseases, but, according to Gibson, there is a filterable virus which is the underlying cause. One point upon which Dr. Flexner had perhaps not laid enough stress was that there were many more hemorrhages in encephalitis lethargica than in poliomyelitis. The aphagia, however, was more prevalent in poliomyelitis than in the other disease. Dr. Strauss said he had studied the brains, though not as yet the cords, of these cases and had encountered the lesion so well described by Dr. Flexner. There was more hemorrhage in the cortex, but without perivascular infiltration. In one case, the report of which was published, an unusual feature was the high temperature; the brain showed marked invasion of the meninges, with punctate hemorrhages. Cultures from the brain gave an aerobic and an anaerobic organism; in one case there was probably streptococcus contamination. A monkey injected intradurally and intracerebrally became ill in three days, but this animal had been used in surgical experiments and was not in tiptop condition. It became weak and lethargic. When killed, a hemolytic lesion was visible at the site of inoculation. Of three other Macacus monkeys injected, one became ill and recovered; two others showed no sign. One animal injected with washings of mucous membrane of a patient became ill and suffered paralysis of the hind legs within 8 days; after 11 days it recovered. The various inoculating preparations were passed through a Berkefeld filter. One animal inoculated developed meningitis and examination showed hemorrhages in the cortex and in the pons. A monkey that had recovered was inoculated with an emulsion very virulent for rabbits, and this animal remained well. A baboon, an animal much more resistant than the Macacus monkey, was inoculated subdurally with the same preparation and became very ill. They could substantiate Dr. Flexner that this disease was not poliomyelitis, but they felt that they had produced a filterable virus which had given lesions similar to those in human beings; it remained to decide what this virus was and its relation to encephalitis.

Dr. ALEXANDER LAMBERT of New York referred to the mask-like appearance and a flattening of the face very similar to that seen in tuberculosis meningitis, which was noted in encephalitis lethargica—a wax-like appearance of the countenance, which was a very striking symptom.

Etiology of the Pneumonias.—Dr. RUFUS IVORY COLE of New York presented this subject. He said that there were objections to employing the term "pneumonia," as pneumonia, even lobar pneumonia, is not a single clinical disease. The word was first used as an anatomical term, and had now come to mean an involvement of the lung, without taking into consideration the parasitic organism implicated. The reaction of the human body to the organism was not the same as that

which took place with the diphtheria bacillus, with which, although there were variations in kind and virulence, the body reaction was identical in all cases. With the pneumonias, the four groups of organisms produced different reactions, therefore in the immune reaction it was necessary to determine the type of organism. The relative frequency of the different types was noted in a study of 700 cases: Of type I there were 35 per cent.; of type II, 30 per cent.; of type III, 10 per cent.; of type IV, 25 per cent. Therefore acute lobar pneumonia could be described as a group of infectious diseases In the pathology the conditions became more complicated; the relation of the bacteria to the pathological lesions had to be determined. Pneumococci were not always found in the lung of lobar pneumonia and that brought confusion into the subject; they could be associated with the bronchopneumonia of children or the terminal bronchopneumonia of adults. Then again the exact relation of the Friedlander bacillus to this lesion was not yet determined; in certain cases they were the only bacteria in the lesion, though sometimes associated with other bacteria. In one case these were in the lung and the circulating blood as early as the fourth day. In three cases out of 144, this organism was the only one present; in these the clinical symptoms differed slightly from the ordinary type. With more frequency the *Staphylococcus aureus* was found as the only organism, and in these cases necrosis of the lung with abscess formation was found. The streptococci and the *B. influenzæ* were long known to be associated. The etiology of the pneumonias could be described as a train of events disrupting the physiological balance of the individual and many features were concerned in this attack. One individual remained healthy; another succumbed to the infection, and the disease could occur without the organism. Pneumococci had been supposed to be normal inhabitants of the human mouth and it was thought that the individual became infected from his own mouth; but study of the subject showed that types I and II were not found in the normal mouth but were only associated with the presence of disease. As little as 1/1000 c.c. injected into the trachea of monkeys produced the disease. Another factor was the variation of virulence. After animal passage the pneumococci became more virulent but after culture in artificial media they became less so. Then both animals and men had a considerable degree of natural immunity to the pneumococci and most persons acquired immunity to the pneumococci in their own neighborhood, but, as was noted in S. Africa and in Panama, the frequent immigration of new laborers to a locality subjected them to infection to which they were not immune. However, when the population became permanent, they quickly acquired an immunity. At San Antonio there were many atypical cases caused by hemolytic streptococci, and although measles cases were rigidly excluded, there was an epidemic of streptococcus lung lesions. This was spread by the fact that the men left the wards still harboring pathogenic bacteria; they were careless about coughing and spitting, and the unusual conditions of crowding and of fatigue increased the spread of the contagion. In regard to the epidemic of the past winter, it was not so difficult to account for it as might be supposed. It was probably due to an infecting agent affecting a susceptible population. This agent might be either a filtrable virus or it might be the *B. influenzæ*. MacCallum had come to the conclusion that the system was first attacked by a filtrable virus which lowered the resistance, and the body then became infected by secondary organisms. There were probably many more lung lesions in the past epidemic than were supposed. The high mortality was due to the high virulence of the organisms, but how much part the *B. influenzæ* played in the epidemic is not clear; possibly it was an important one. In conclusion, Dr. Cole said that the pneumonia in an individual occurred from a combination of circumstances and the epidemic could also be said to arise from a combination of factors. To focus attention on one point to the exclusion of other factors was to ignore the possibility of a complete understanding of the subject.

Treatment of the Pneumonias.—Dr. CHARLES FRANKLIN HOOVER of Cleveland, Ohio, made this presentation, by invitation. The speaker said that a cure for pneumonia might be found, although there was no cure to be had for pneumococcus infection. This view should not be startling to the profession, as they already had similar examples. In the Poynton and Payne infection of the joints, for instance, the synovitis would subside wonderfully with administration of large doses of salicylates, but the patient could have at the same time an endocarditis, a myositis or an endophlebitis, due to the same organism, which were in no way affected by the salicylate dosage. The same thing could be observed in syphilis; gummata of the skin, of the liver, could be cured by dosage of iodide of potash, but this drug did not cure the syphilis. Iodide of potash will restore gumma of the liver but not the syphilis at all, although it was only recently that the medical profession had learned this fact. In regard to pneumonia, in a very large proportion of cases the pneumococci had been recovered; there were the evidences of chill, fever, and isolation of pneumococci from the blood, before observation of the lesion in the lung. Thus, there could be general infection, without the local pathological process. In one patient seen by the speaker a profuse hematemesis which almost exsanguinated him was the first indication of the pneumonic infection. At autopsy a few days later, extensive pneumonic lesions of both lungs were found. In another patient, an old man, a hematuria was the first symptom of the infection. Another of the early evidences of the infection was the icterus. An interpretation of the color of the sputum would be of help here. A "rusty" sputum was simply a sputum colored with the patient's transuded bile, and tinged with blood pigment. After washing the blood from the sputum a clear yellow sputum retained, and if a blood specimen were now taken and freed from red cells, the clear plasma would be found to match the yellow sputum, that is the bilirubinin was found to color the plasma. There was not enough, however, to dialize bile salts in the blood plasma. In this case one was dealing with a genuine hemolytic icterus which was a very early manifestation and the hemorrhages seen were but an expression of a severe hemolysis. These patients generally got over the icteric stage before they came into the hospital. Dr. Hoover said that when he was a medical student there was a phrase in use "bilious pneumonia." It was supposed then that the right lobe of the liver did not completely pump the bile out of the liver, and this statement found its way into many of the text-books, and was accepted as gospel by the students. In regard to immunity, it might not be possible to confer immunity against the pneumococcus, but one had to ask what was the character of the acquired immunity and what was the protective substance. The side-chain theory of Ehrlich had come to be received with as much reverence as the decalogue and it was argued from this that the protective substance must be in the blood plasma and nowhere else. That this protective substance might not lie in the plasma, but in the cells or some other organ, could be shown by the following experiment. Animals had been injected intravenously with a large number of pneumococci, and after this part of the vessels were tied off. It was found that in the freely circulating vessels the organisms were very quickly disposed of, but on opening the tied off vessels, the same quantity of bacteria were found without any change. Therefore it would seem that the bacteriolytic substance was not independent of other cell structures. In the liver the large Kupffer cells had been found to engulf several hundred streptococci, thus it would seem as if the cellular protection of these fixed phagocytes were greater than that of the wandering phagocytes and that they could confer protection upon the animal. The profession were getting away from the idea that there had to be a certain titer between toxin and antitoxin in pneumococcus infection. In the papers to-day no cure had been mentioned, because no drug was known to cure pneumonia. One had to consider other means of treatment. Cyanosis might be a very important factor to consider, and one had to study the reason for it. In pneumonia there might be consolidation of, say, one-fourth of the lung; thus, though circulation continued, one-fourth of the lung had unrespired blood and increased CO_2 content, but by giving a patient oxygen the anoxemia was not compensated; the man was not suffering air hunger, although he had cyanosis on account of the

high CO_2 content. It was necessary to examine this matter, because the medical man only saw what he looked for, unless he looked for elephants, he did not see them. One had to consider that the respiratory membrane was very extensive, and would cover several hundred square yards if spread out, a large area over which to spread a few ounces of blood. In a moist condition of the bronchioles, with surface edema and moisture outside of the air spaces, the giving of oxygen would cause an oxygen foam which would allow the passage of oxygen to the lung after three or four minutes, but in deep edema of the lung, there was no benefit to be derived in giving oxygen at all. It simply did not reach the lung.

Dr. Augustus Wadsworth of Albany said he had been much impressed with Dr. Cole's presentation dealing with the different factors which contribute to the development of pneumonia. He thought that all of them had put too much stress on the inciting agent in the disease and had allowed other factors to fall into the background. The conditions that affected the development of pneumonia acted in two ways: either by the virulence of the exciting agent or by the susceptibility of the person. The virulence varied in the different diseases; in diphtheria there was marked toxic poisoning; in pneumonia there were toxic symptoms, but one had not been able to recognize the poison. Cultural conditions affected the toxicity of the organism. Thus, simple culture in broth increased the virulence in 24 hours, apart from animal passage, so that growth and vegetative powers were important factors. Susceptibility of the individual was also important and this was clearly emphasized in the experimental study of animals' susceptibility to pneumonia. In those that are less susceptible, different types of pneumonia were found. The pneumonia was really the expression of the power of the animal to react to the poison; with slight poisoning, the reaction was slight; with increased toxicity the reaction was increased. The two sides of the balance had to be considered—the virulence on the one hand, the susceptibility on the other. The word resistance was a vague term which could be more clearly expressed by the word susceptibility. The skin, and also the lungs, to a certain extent, formed a barrier to infection; thus it was seen that infection was apt to pass directly from the trachea into the circulation. In regard to the pneumococci and the streptococci, this group of infections was important, but the English writers had noted that influenza was often fatal without pneumonia, and that the severity of the influenza had nothing to do with the pneumonia, because often very slight lesions of the lung were associated with virulent infections. The influenza greatly lowered the resistance of the individual. The symptoms were marked toxemia and prostration and when influenza pneumonia occurred it was characteristic both pathologically and clinically. Pneumococcus infections often developed in the course of streptococcus infections. Dr. Hoover talked about early infection in pneumonia; it was to be presumed that the doctor did not mean that the organisms reached the blood first, but that the organisms reached the blood from the air spaces. As for the protective substances in the plasma (or blood serum), it could be demonstrated in vitro, that organisms put into immune serum at 36° C. would grow, but at 41° C. they were destroyed by hemolysis. Pigeons and chickens with a normal temperature of 41° C. were unsusceptible to infection. Thus temperature was an important factor. In regard to serum treatment, this had been tested out for four years, and the figures showed that the mortality for the treated cases was a little higher than for those not treated, in the rural districts. In the Army, at Camp Wheeler, of 72 cases treated, there was a mortality of 8.2 per cent., nearly as low as the Rockefeller Institute mortality of 7 per cent. Proper serum treatment might be very efficacious. The usual mortality was 20 per cent. The big medical centers gave the best figures in this respect, and serum treatment, if done at all, should be done thoroughly.

Dr. Loewe of Mt. Sinai Hospital, New York, read a short summary of a method to determine the types of pneumococci by blood precipitation tests. This was found superior to and more exact than typing by sputum methods. Only 5 to 10 c.c. of blood were required and the various types, as well as the mixed infections, were more easily determined.

Dr. F. B. Turck of New York said that he was proud that America could boast of Dr. Cole's work in the study of the pneumonias. The pneumonia commission had taken a conservative standpoint. Further investigation into methods of treatment was necessary. The speaker had found that autolysed lung tissue of the same animal was the cause of the lung lesion, and not any organism. Animals had been known to die in a few minutes after the aspiration of this substance into the bronchi. In experiments on cats, the animal's paws were covered with paste made of autolysed lung tissue, and most of the animals died. The secondary invaders were not the cause of the lesion.

Dr. E. Libman of New York said that he had followed up the work Dr. Loewe had mentioned. It had been found that if one put pneumococci in normal serum there was a slight acid reduction. In the serum of a pneumonia patient there was a precipitation and coagulation, and evidently there was something in the serum by which carbohydrates could be broken down and acid formed. The product in the serum of pneumonia cases was found to be specific for the various groups. In regard to the serum treatment of patients, the serum in many cases was not properly given, and it was necessary to have a specially trained man for its proper administration.

Dr. Cole, in conclusion, said that he hoped that Dr. Hoover did not want to say that serum had not protective value. They could not overthrow the fact that immune serum is protective. In regard to serum treatment, it had to be given right, just as quinine had to be given right in the case of malaria, although there was, of course, not much analogy in the two methods. It was hoped that in the country districts in time that immunity might be obtained.

Dr. Hoover, in conclusion, said that he did not refute the fact that the use of serum of an infected animal might be essential, but medical men had come to think that the protective substance was to be found in a certain titer of toxin and antitoxin, but the serum of an immune animal could not protect against anaphylaxis or hemolysis. Another factor to be remembered was this, when one had a specific factor in any disease, the specificity became apparent immediately, but when the specific employed gave rise to such a great amount of scepticism as the use of serum treatment had done, it raised a question as to the real specificity of the agent in question.

Influenza.—Dr. Alexander Lambert of New York presented this subject. As early as 1137 an epidemic was recorded which spread from Eastern to Western Europe. Various epidemics had been noted and in the past century Prof. Theophilus Thompson gave a detailed report of an epidemic which he described as the most extensive and least liable of modification, so much so that it was superior to national habit and impaired the vital energies of the victims so that they suffered an increased liability to other diseases. In 1510 Dr. Thomas Short described a malady called the coqueluche (from the hood which the sick drew over their heads), which came from Africa and ranged over Europe and which was signalized by headache, chills, distress, and cough. Children died of it in some instances. To-day the disease could be described as characterized by headache, pain in the bones, cough, and prostration out of all proportion to the severity of the symptoms, the patient taking a long time to recover from the exhaustion induced by the disease. One point noted was that in the height of the attack young and robust persons suffered, but later in recrudescent stages of the epidemic, older people became victims. One attack apparently did not produce immunity against another, although it was possible that the infection lingered in the sinuses and tended to produce recrudescences which were mistaken for new attacks. The disease was spread from one to another by spraying of infected particles through coughing and spitting; the lachrymal sac was supposed to present a large area for infection and bacteria were found to pass to the nose in five minutes and to the throat in 15 minutes, from this point of origin. Opinions varied much as to the probable relation of the bacillus of Pfeiffer to this disease. Some thought it due to a filterable virus. The organism of

Pfeiffer was found in enormous numbers in influenza cases; it was an anaerobe and not easy to cultivate. Since the technique had been improved, more cases of the bacillus of Pfeiffer had been identified. It was a gram positive coccus, which was able to pass through the Berkfeld filter, and had high resistance, being able to survive a temperature of 56 deg. C. for 30 min. The English workers had cultivated the organism from the blood and exudates, also pleural fluid and cerebrospinal fluid. By Noguchi's cultural method coccoid forms were isolated, probably pleomorphic in character; thus, the germ might be a facultative anaerobe with varying growth, according to whether there were oxygen or not. The different types described might well be different forms of the same organism. A certain amount of immunity seemed to have been produced to this germ. It would appear that the pneumococcus was a secondary invader which entered after the primary organism had destroyed all resistance. In British India alone five millions of people had died within a space of two months from the disease, the natives being particularly susceptible to its ravages. The sodden lung, characteristic of these pneumonias, had been described in the eighteenth century, as a bloody transudate. It was found associated with severe myocardial degeneration, especially in patients of over 60 years of age. In regard to treatment, vaccine, if administered early seemed to provide immunity in the majority of cases. Injections intravenously of 800 millions of typhoid bacilli had been given, which were followed by a typical protein reaction, a sharp rise in temperature and improvement. Salicylates could be given to relieve the distressing pains in the bones, but the antepyretic coal tar preparations seemed to be contraindicated. Persistent spraying of the pharynx tended to prevent the spread of the disease downwards from the pharynx. The absence of physical signs in extensive bilateral pneumonia was a marked feature of these cases; slightly diminished breathing, with a few râles and harsh breath sounds were, as a rule, all that were heard in these cases and must satisfy the most exacting as a guide to differentiate these pneumonic lesions.

The Aural Complications.—Dr. Edward Bradford Dench of New York made this presentation. He said that in an epidemic it was difficult to obtain data as to special organs. Medical men were under an unusual amount of work and they were not trained to determine complications of special organs. In St. Luke's Hospital, in the period of time from Sept. 1, 1918, to March 31, 1919, there were 30 cases of middle ear involvement of which 2.7 per cent needed mastoid operation. This was slightly less than the number of cases for the preceding year. It was essential that cases of middle ear involvement should be recognized early. Temperature should be noted in infants, and pain and temperature in adults. The physician, however, should not attach too much importance to slight changes, as, with many infections, a spontaneous subsidence was noted. In many cases with mild congestion of the drum membrane, the drum had been unwisely opened, laying it open to chances of infection. It was only necessary to do this in cases of acute pain. During the epidemic the infecting organisms noted in the ear had been usually the streptococcus or the pneumococcus, no hemolytic streptococci had been noted, however. In ten mastoid cases in children under 8 years of age the pneumonia was of the bronchial type, and it was difficult to determine whether the temperature was due to the chest or the ear. It was difficult to employ general anaesthesia for the mastoid operation in these cases. One case was fatal, in which a late meningitis developed after operation. An early operation would have saved the patient. The general practitioner should be on the alert for complicating aural lesions, as early involvement of the middle ear was always a danger signal.

Dr. Roby of Rochester, N. Y., said that he had listened to some remarks about intravenous injection. He had found this to be a very dangerous procedure in many cases; where successful, it was most brilliant, but one ran a great risk. He had seen one patient who ran a temperature of 109 after the injection; she died two hours later. On the other hand he had seen a case of influenza with a persistent temperature that really looked like a four weeks typhoid. The temperature was 105 and after an intravenous injection it came down to normal by the next day.

Dr. F. B. Turck of New York said that Dr. Lambert had brought out the point that there was very little evidence of infection in the extensive pneumonic infection. In experimental animals it was found that there was congestion of the lungs, that it was in the lungs that the first reaction took place. The transmission in these cases had been found to be due to hand-to-hand transmission, rather than to coughing and spraying.

Dr. J. F. McCaw of Watertown, N. Y., said that the cases of otitis he had seen were those that went on to convalescence without radical interference. The hemorrhagic type occurred at the height of the epidemic and was more severe than the type that followed the epidemic. In one patient there was pus in the kidney and hyaline degeneration, when this was cleared up one might hope to clear up the ear condition.

Dr. Charles of Queens said that he hoped to hear about vaccine treatment. He had had very satisfactory results with autogenous vaccines of *B. influenzæ* and of *Streptococcus hemolyticus* the temperature of the patients had been brought to normal in a very short time with alleviation of the symptoms.

Second Day—Wednesday, May 7.

Dr. Malcolm Sumner Woodbury of Clifton Springs in the Chair.

The Present Conception of the Significance of Cardiac Phenomena.—Dr. Allen Arthur Jones of Buffalo, N. Y., made this presentation. He stated that the older writers had a large knowledge, not only of valvular disorders, but also of the rôle of the myocardium, and thus they were able to lay down sound principles of treatment in cardiac disorders. There remained, however, the large field of pathology and clinical behavior to be understood. Studies of physiology of the heart brought out the importance of the nodes, and of the excitability and contractility of the heart. Later, the use of instruments of precision, such as the sphygmograph, introduced the study of arterial tension and the volume of the pulse. This instrument paved the way for the polygraph and the sphygmomanometer which registered arterial pressure. The development of blood pressure studies emphasized the difference of pressure in the arm and the leg, which, in aortic insufficiency, might be as much as 130 mg. in the leg as compared with 60 in the arm. Studies showed that in five out of ten cases no diastolic pressure could be read in the leg, whereas in the arm a pressure of 60 to 80 mg. was recorded. Later the electrocardiograph, with the tracings of the cardiac cycle and heart murmurs had led the way to a deeper understanding of the physiological and pathological cardiac phenomena. Post mortem studies had corroborated the knowledge gained clinically, and had afforded data of the first order. The clinical and pathological conferences as advocated by Thayer and others had done much to add to the understanding of cardiac disease as the autopsy studies had explained the bedside observations. In regard to various forms of cardiac pathology, Dr. Jones said that pathological bradycardia indicated disease of the auriculoventricular bundle, perhaps with sclerotic changes in the bundle which were not syphilitic in origin. The Adams-Stokes syndrome and heart block, although studied, were not yet fully understood. The arterialization block was an interference of the auricular impulse coming through the main bundle. The seriousness of the complex would be understood when it was stated that of 112 patients, 69 per cent. died within 12 months. In paroxysmal tachycardia, the heart was under the influence of a new focus of contraction, removed from the normal pace-maker. This pathology was associated with endocardial and myocardial phenomena and with pulmonary and renal disease. Sometimes, however, it occurred solely through disturbance of the neuromuscular mechanism. Auricular flutter should be differentiated from paroxysmal tachycardia. The treatment consisted in giving digitalis or strophanthus in large doses, which would change the pathology into auricular fibrillation. MacKenzie, in his studies on dilated heart, had stated that in the broken rhythm

the impulse was disturbed in the auricular-ventricular node and the ventricular contraction would precede the auricular by one-tenth of a second. As regards etiology, the rôle of focal infection in cardiac disease was fully appreciated at the present time and the cardiac condition often cleared up upon its removal. Acute articular rheumatism, gonorrhea, and septicemia were known to be associated with cardiac conditions. The present war had tended to throw much light on the behavior of the heart and circulatory apparatus under varying conditions of stress. Enthusiasts were put upon their mettle to explain conditions, and many mistakes were naturally made, but men were kept under test observations to determine the circulatory data in different individuals. There was established, in reality, a nation-wide heart clinic and many things were learned. Hearts with murmur could be made into new hearts, capable of enduring heavy work. Four things, however, were essential: first, endocarditis must have ceased; second, the myocardium must be intact; third, the heart must not be subjected to focal infection, or intoxication such as syphilis or thyroid hypertrophy; fourth, it must be of normal size. In myocarditis or aortic insufficiency the heart was sure to break down under strain. In cases of atypical hyperthyroidism many men were rejected, and many other men broke down; it was proved that the thyroid heart would not endure strain. This type was seen in thin, young individuals, with more or less marked gastroptosis; the arteries appeared tense, but the blood pressure was low; and the heart commenced to pound on moderate excitement. This type represented the neurocirculatory asthenic, and the men were poor subjects for first line service. They were apt to present dizziness and mental confusion under stress. The treatment of this class was: first, by removal of focal infections; second, relief of gastrointestinal stasis (an important element in these cases). Careful and sympathetic training under an experienced medical officer was a prime essential, as judgment and technical knowledge were necessary to appreciate the condition and estimate the limitations of these subjects. In serious cardiac lesions the treatment called for complete rest, and the Carrel diet (800 c.c. of milk in 24 hours); also the Eggleston method of quick digitalization was of much value. The dosage was .145 c.c. per pound of body weight. This, however, was not a safe procedure unless the patient could be kept under constant observation, which practically limited such therapy to hospital practice; 0.5 mg. doses of strophanthin could also be given under the same conditions.

"Analysis of Cardiac Conditions in 66,575 Drafted Men Examined at Camp Gordon, Georgia."—Major ANDREW MACFARLANE of Albany, N. Y., read this paper. He said that in the army camps the thing that struck the doctor was that conditions were to be dealt with by wholesale—by thousands and by tens of thousands. It was a question of speed; things *had to be done.* A year ago the country was in the terrors of war and the necessity was to get men to the front, no matter at what cost. Conditions were obviously unsatisfactory for a thoroughly satisfactory examination of the patient. The motto of the army was "To hell with science; we want speed." Thus an enormous number of young men between twenty and thirty years of age, and from all sections of the country, were examined, and the statistics gleaned would show more or less interesting facts. 373 men were immediately discharged for marked cardiovascular lesions. Statistics showed similarity of figures for all the States, excepting Iowa, in which the men presented one-half the physical disability of the men in other States, and averaged the best physical types of the men examined. Of the cardiovascular lesions discovered 86 cases were of mitral insufficiency; 24 of mitral stenosis; 26 of aortic insufficiency; 1 of aortic stenosis; 34 of myocarditis; 56 of hypertrophy with hypertension; 5 of hypertrophy without hypertension; 76 of persistent tachycardia; and 49 of irritable heart (neurocirculatory asthenia); 1 case of adhesive pericarditis; 1 of aortitis; 1 of brachial aneurysm; 1 case of marked anemia with anemic heart. An interesting point was that two cases of dextrocardia were noted—one in general examination and one was remarked because of a right varicocele which drew attention to the fact. The ratio was three cases of dextrocardia to 100,000 persons. The cases were not rejected. Cases of mitral regurgitation without hypertrophy were accepted when there was no accentuation of the second pulmonic sound. Cases of myocarditis with history of severe infection and poor sounds were found very poor subjects. A systolic pressure of less than 150 was considered hypertrophy without hypertension. The conditions under which the men arrived were not ideal for accurate examination. The long journey, the crowded cars, the often injudicious eating and drinking with hospitable friends before they left home, made the detection of a true tachycardia difficult. Fifteen to eighteen hundred recruits had to be handled daily. The preliminary examination was made in a large, noisy room. The upper room, where the special tests were made, was also noisy, and the sounds of cars, drilling, and bands playing had to be disregarded by the medical men. Examinations had to be concluded the same day. Each examiner had to look over 250 men and no accessory aids to diagnosis were possible. The precordium and vessels of the neck were examined and a reauscultation after exercise was done. Three-tenths of the men examined were referred to the special examiner, and one-sixth of these latter were declared to be unfit for military duty. In spite of the noise and confusion it was surprising to what proficiency the examiners attained and it was found that of those who were passed only a very small number broke down, although the subsequent training took place in the hot weather, in Georgia, the three months' course was crowded into six weeks, and the men were driven from early morning to late at night. In regard to types of lesions diagnosed, they included mitral insufficiency, mitral stenosis, and hypertrophies. The mitral stenosis cases were in poorly developed men, in whom a definite presystolic murmur was noted after exercise. The double mitral lesion, sometimes seen, made this more striking. Aortic insufficiency cases usually gave a history of heavy work; syphilis was noted in 30 per cent. of these cases, with a definite diastolic basal murmur in every case; there was also marked hypertrophy of the heart. Of 26 men between 21 and 25 years of age, 19 were discharged. The myocarditis cases responded poorly to exercise. The hypertrophy and hypertension cases showed a high blood pressure, although the ratio was normal. It was necessary to distinguish the irritable heart cases from persistent tachycardia. In the irritable hearts, the history of syphilis was infrequent. There were noted marked cyanosis, cold hands and feet, tremor, marked tachycardia, apical thrills, accentuation of the second pulmonic sounds, often high pulse pressure. In the simple persistent tachycardia cases, on the other hand, nervousness and cyanosis were not noted, nor were tremors felt; thrills were rare; and the blood and pulse pressure were less than in irritable heart. It was interesting to note the percentages of failure in diagnosis both in the preliminary diagnosis and in that made by the referees: these approximated 1 mistake per 2,000 men—that is, about 100 cases broke down. These included 13 mitral insufficiencies; 8 mitral stenoses; 1 double mitral stenosis; 4 aortic insufficiencies; 20 cases of myocarditis; 4 irritable hearts; and 5 tachycardias. The referees failed to find lesions in 18 out of 2,288 cases referred to them—that is, they failed in one out of 126 cases. If the cases of myocarditis (which the Government ruled should be accepted) were omitted, then the cardiovascular board could be held responsible for 13 failures in diagnosis among 67,565 cases examined.

Dr. WILLIAM D. ALSEVER of Syracuse, N. Y., opened the discussion. He said that it had given him great pleasure to listen to Dr. MacFarlane's admirable paper. He had also been glad to hear Dr. Jones lay emphasis on the use of diet in heart disease; this was one of the best forms of treatment and the profession should make use of it more than they did. Another point was the use of digitalis; he spoke of the method of estimating the dosage which should produce digitalization in the individual. The tincture of digitalis could be given intravenously, and half the dose could be given by mouth. This method would be found as satisfactory as any tried before. The question of murmurs was of great interest. At the meet-

ing of the Climatological and Clinical Association two years ago there was a great deal of discussion on the subject of differentiation and aortic murmurs. It was thought that a soldier who had a murmur should not be sent to active service. Later on, Dr. Alsever said, it had been his privilege to serve in France and he had come to know that the sound of a systolic murmur was not a thing of special importance in estimating the fitness of a man for service—that is, it had no value by itself without other physical signs. MacKenzie had laid down a rule which stated that if on careful examination of a case of heart disease, only one sign could be found, and there was nothing else to corroborate it, the sign could be disregarded. So that, instead of condemning the patient with systolic murmur to a life of invalidism, one could allow him normal exertion. Cases of aortic regurgitation and mitral stenosis would break down inevitably under strain. In one case a soldier, supposedly suffering from "shell shock," was pronounced sound by the neurologists. He, however, applied for a medical examination and it was found that what had been called "shell shock" was in reality aortic regurgitation. The recumbent posture would be found of value in some cases, especially in mitral stenosis, as an aid to diagnosing the condition. The functional murmurs were then best heard. There was one exception to this rule and that was in cases of irritable heart—the neurocirculatory asthenics. These cases of handicap were a real problem. They had been called "effort syndrome," but perhaps "excitation syndrome" would be the better term. It was a mistake to emphasize the heart side of this problem, because sometimes treatment of abdominal ptosis would relieve the condition, and that was clearly not heart disease. All one could say with certainty was that the body easily tired. Some observers believed that hyperthyroidism played a part, because of the rapid pulse and sweating, but as goiter was lacking this did not entirely account for the state. Other workers believed that the trouble was in the endocrinal glands other than the thyroid. Lewis in England had done a great deal of work on the effort syndrome cases, but had not found out anything definite. The causes might be various: either constitutional defects or acute infections, such as tonsillitis, trench fever, pneumonia. Gassed cases behaved very much as cases of acute infection. A bronchitis developed, but there seemed to be a more acutely intoxicating factor. With an excess of CO_2 in the blood, breathlessness was hastened, because it was stimulated by acids. The acid reaction of the blood varied very greatly with exercise and the blood was unable to accommodate itself to the changing acid conditions. Acidosis played some sort of a rôle in these cases. The English workers had reported polycythemia and claimed that the disturbance was in the red blood cell numbers. These subjects as a whole responded poorly to exercise, they did not improve very fast, and it was noted that in effort syndrome the subject could only hold the breath for a short time—about ten seconds, instead of 40 or 50 as in normal men. In the gassed cases, many of which were pitiful, a careful study was needed. They were kept in bed at first, but orders came along to give them exercise. After exercise of half a mile many dropped out from exhaustion and pain in the chest, all the symptoms of effort syndrome. Since his return, Dr. Alsever said, he had had the hearts of these men *x*-rayed and found enlargement of the heart, where there was no suggestion of heart defect before. It could be concluded then that gas did some damage to the circulatory apparatus and much exercise was a mistake.

Dr. JENKINS of Albany, N. Y., said that at autopsy they had an opportunity of judging the pathology in many of these cases. In 100 autopsies he had seen two cases in which the condition of the tricuspid valve had been overlooked. In one case, a young athlete, the man had taken a high jump, after which he fell down in convulsion and died. Autopsy showed a persistent thymus which consisted of two lobes with an isthmus and another lobe. The other case was of right ventricular rupture. This case also had persistent thymus.

Dr. L. F. BISHOP of New York said that he was greatly interested in Dr. Jones' paper, which had covered the subject of modern cardiology in a short time. It would be difficult to discuss such a valuable paper, so that he preferred to present something that might be of value to the general practitioner. In heart practice the electrocardiogram was used as a routine measure, but, in his experience, very few of the profession had made any attempt to understand the electrocardiogram. The reason was clear. It was hard at the start to work out any explanation of what it meant. There was nothing to be found in the textbooks which would give the matter simply. Dr. Bishop had therefore worked out for himself a simple interpretation, because he said he had gone before many medical societies and shown what he considered very beautiful pictures, and had handed them round, but that they did not receive the attention they deserved. The men did not understand what they meant. These tracings were simply an autograph of the heart beat which was transmitted along the wire. The waves were named P, Q, R, S, T. P, R and T were the principal waves and represented the current generated by the contraction work of the heart. The auricle was a soft structure which received the blood under no particular pressure, and when the heart contracted in diastole the blood was pushed into the ventricle. Thus P denoted auricular contraction and work. In the next step the ventricle had been filled with blood, and the heart was ready to do its real work of circulating the blood. The illustration of a man falling flat on the water was given to show that fluid does not immediately yield to pressure, and in the contraction of the heart on the amount of blood in it, the fluid did not yield immediately, but the heart had to contract on it before squeezing it into the circulation. This was the R wave. The T wave was the work of the heart squeezing the blood into the circulation. Thus:

P=contraction of the auricle.
R=contraction of the ventricle.
T=work of the ventricle.

The waves Q and S were not of importance, being probably reflexes from the other waves. This would give a starting point from which to commence an intelligent reading of the electrocardiogram.

Dr. L. T. LEWALD of New York said that the observations of cases of dextrocardia were very interesting. He had been examining cases for ten years and had personally seen 19 cases. The examination of recruits with the fluoroscopic *x*-ray brought the percentage of cases up. Compared with the population of the world every one in Syracuse would have dextrocardia. It would seem as if many cases had gone unrecognized in the past. It was interesting to note that one case had been detected by a right-sided spermatocele. Probably there was complete transposition. The exact study of the size of the heart had become more general. The soldier's heart was found to be larger than the civilian heart. Dr. LeWald said he had been making studies on aviators' hearts at the Mineola Camp. It was a question whether the heart dilated when the aviator ascended 30,000 feet. It was believed that it did in a large percentage of cases. Studies were made on three men by *x*-ray observations. These were made by means of a low pressure tank in which an exhaust of the oxygen simulated the conditions of high altitude. The whole problem was one of diminished oxygen supply. In order to take the *x*-ray, a window was cut out of the tank and replaced by an aluminum sheet, 5/16 of an inch thick. Satisfactory radiographs were made through this window at a distance of 80 inches from the plate. Care was taken to have the ray strike a certain portion of the spine and thoracic vertebræ and to take the pictures in the diastolic phase of the heart. Another point was to get rid of the effect of respiration on the size of the heart, noting carefully whether the examination was during inspiration or expiration. In many cases the patient was in a fainting condition. The heart was taken during expiration. The movement of the heart was about 2 c.m. It was difficult to measure exactly the lower border of the heart, although an excellent radiograph could be obtained of the apex. It was necessary to have the subject drink mineral water to bring a gas bubble into the stomach.

Dr. ARTHUR A. JONES, in closing the discussion, said that he was grateful to Dr. MacFarlane for his extremely valuable contribution. In the cases of neurocirculatory asthenia noted, Dr. MacFarlane had found high blood pressure. Dr. Jones said that in his own paper he had stated the blood pressure as low, and these seemed contradictory observations, but if the subjects were studied under varying conditions—that is, under the tension of military examination, and also under quiescent and relaxed surroundings, the difference in blood pressure would be accounted for. These patients reacted enormously to the slightest stimulation, the blood pressure rising 40 points in a few minutes. The blood pressure could be called unstable rather than persistently high. This excessive reaction gave rise to a persistent teasing of the circulatory apparatus and they easily developed a cardiofibrosis. Dr. Alsever's remarks upon the work of Lewis, and upon his own work in England, were interesting. The question of acidosis played a large part in cardiovascular and renal disease and it might be that one should consider more carefully its relation to these cases. Dr. Jenkins had reported most interesting cases of status lymphaticus. Personally, the speaker said he could not disconnect a right-sided myocardial lesion from the status lymphaticus, yet there was no actual scientific explanation of that. Dr. Bishop did well to call the attention of the members to the reading of the electrocardiogram. These tracings were difficult to appreciate, but they were as nothing as compared with the difficulties of the polygraph. It was surprising to hear from Drs. LeWald and MacFarlane of the number of cases of dextrocardia. It would seem that one should be on the lookout for them. Most practitioners had examined many cases by physical and by *x*-ray methods without having discovered one of them. In conclusion Dr. Jones said he felt that Dr. LeWald was doing such splendid research work on the size of the heart that he felt his own contribution had been very small in comparison.

Dr. ANDREW MACFARLANE of Albany, in closing, said that he had been in such haste to cover his subject that possibly he conveyed a wrong impression. He had not meant to say that in neurocirculatory asthenia the blood pressure was high, but that it was high in comparison to that associated with paroxysmal tachycardia. There was marked debility of the pulse blood pressure. One felt, in a great many ways, that the war had stopped a little too soon. The soldiers would have been glad to have it last longer. At Camp Gordon Dr. MacFarlane said he had just got a good laboratory in full swing and had begun to make blood chemical examinations. They found the blood of the neurocirculatory asthenic to be apparently increased in the content of sugar, urea, and creatinin. There was nothing unusual in these subjects, but Uncle Sam demanded 100 per cent. men and these men did not measure up to the mark; when it came to going over the top they were substandard. In civil life they were not remarked, they chose easy jobs, drove a wagon or ran errands, but in the army they had to go from 5 in the morning to 11 at night and they fell down. They were the kind of whom the mother said "he has outgrown his strength," but the Government could not pay attention to that. One had to look, however, for the underlying cause and find why a lad outgrew his strength and what was the reason for the substandard. It was pathetic to see the number of men thrown out by examination and unable to take their place among the others as American citizens. More trouble and humiliation were suffered by those who were willing and who were found unfit, than by those who tried to evade the draft. There was a great possibility for the medical profession to carry out some scheme of prevention in these cases, without waiting till war came to find out thousands of defects occurring in young men under thirty years of age.

A Program for the Development of Internal Medicine in New York State.—Dr. AUGUSTUS WADSWORTH of the State Board of Health of Albany, N. Y., made this presentation. He said in the preparation of this paper he had probably gained more than the members of the society would. A careful study of the subject of how the laboratory might be of service to the State was an education. Preventive medicine had been greatly enlarged in scope and, aided by the science of bacteriology, had reached out in various directions, which affected the modern social organization, such as sanitation, cleanliness, removal of nuisances, care of water supply, disposal of sewage, methods of protection, and development of laboratory facilities. The Department of Health protected the citizen by doing for him what he could not do for himself. His food and drink were safeguarded; his waste disposed of; and precautions were taken to protect him from communicable disease. Infectious diseases formed but a comparatively small part of preventable human ailments; the diseases of adult life, constitutional disorders, occupational disorders, psychic disturbances, structural deformities were all, to a certain extent, preventable, and this fact was fully recognized by public health officials. Various attempts were being made on all sides to improve conditions that affect health and happiness, and there was a demand for new adjustments of social organizations. Education perhaps was the first essential towards improvement. It was difficult to enforce sanitary regulations that the people did not understand, and so the educational work of health departments became indispensable. Both the profession and the laity were alive to the necessity of preventional methods; the School of Hygiene at Johns Hopkins and the School of Industrial Hygiene at Harvard were striking examples of professional interest. Social welfare work showed the awakening of the public conscience, and health insurance was an attempt in the same direction, although, as framed in England and Germany, it was subject to abuse, and the more competent physicians were not chosen to give advice. It was simply lodge practice perpetuated, and was not what its name connoted. This system of "sick benefits" (as it really was) had no effect on mortality or morbidity, and was simply a fetich which appealed to the misinformed public conscience. Legislators in this country would do well to see the dangers of this practice. Industrial medicine was on a different footing, as here were employed well trained physicians, nurses, and laboratory experts. The scope of these organizations might be extended with the cooperation of the department of health and the efficiency would be increased as the organization developed. Industrial medicine had received unqualified support from every quarter, its only drawback was that it did not apply to employees of small concerns, and there was no way of reaching all the people except by developing the health department. Unfortunately in New York State the efforts at expansion of the health department had met with the discouragement of the profession. The purpose was misunderstood. Dr. Biggs had proposed to establish centers to put laboratory facilities at the service of physicians, but doctors thought they were to be supplanted and so opposed the scheme, the result being that without such aid many communities would soon be without physicians. The establishment of such laboratories throughout the State would standardize the methods of diagnosis and meet the problems of preventive medicine in each district. Cooperation with institutions and hospitals and with industrial medicine would tend to increase the efficiency of every physician of the State. Signs that this conception of welfare work was being broadened were evident in the appearance of columns on industrial hygiene in the medical journals and at least one magazine devoted to industrial hygiene. These were stirring times and every one was on the alert, and sometimes apprehensively so. The medical profession, especially those engaged in public health service, legislators social workers and those who mould public opinion, should be ready to meet the emergency.

Dr. CHARLES STOCKTON of Buffalo said that he would have liked very much to have had a few hours in which to consider the subject and correlate his ideas before attempting to discuss it. Many of the subjects which Dr. Wadsworth had suggested were growing in various parts of the State and of the nation at large, and Dr. Wadsworth was but forecasting the movement which was bound to take place for the betterment of the study and practice of medicine under the guidance and control of the State authori-

ties. They had learned through the work of the draft boards and the medical advisory boards of the necessity of some such coordination in the attempt to reach numbers of people who were drifting into wrong channels. All who had been engaged in such work felt that they had learned many lessons and that the matter should be dealt with and brought to some real concrete result along lines such as Dr. Wadsworth had dealt with in his paper. Whether the work would have to be done entirely under State control would have to be studied, but at present it would appear that nothing better had been thought of than the plan that the State Board of Health should control the activities. The matter was of the utmost importance and great future developments could be expected from Dr. Wadsworth's suggestions.

Dr. L. F. Bishop of New York said that this matter of the relation of medicine to the social fabric was a difficult question. He felt that Dr. Wadsworth's paper had been most enlightening. No doubt there was a great deal to be learned from industrial medicine. In the past winter at the Academy of Medicine there had been much discussion on the treatment of influenza. There was no standard of therapy. Some urged keeping the patient warm, some believed in opening the window and freezing the patient. The speaker himself advocated a certain line of treatment. Afterwards a man came and sat down beside him, an ordinary man of no particular distinction, and began to talk. He said he was the medical director of an industrial organization and had charge of 100,000 employees, and had several subordinate doctors under him. The firm had just issued a circular on the treatment of influenza, which was along the lines that Dr. Bishop indicated. There was an instance in which a standard method of treatment could be applied to 100,000 employees, and it was this man's duty to find the best means of carrying it out. The State Health Department would have a wonderful field of usefulness if it would standardize measures to be applied in emergencies. The thing that would appeal to the public most would be the money value of the idea. Insurance companies and industrial organizations had saved hundreds of thousands of dollars by taking care of the workers. This fact had to be brought home to the public in order to popularize it.

Dr. T. H. Allen of New York asked if Dr. Wadsworth condemned health insurance.

Dr. M. S. Woodbury of Clifton Springs (chairman), said the speaker did and he hoped that Dr. Wadsworth would emphasize this fact.

Dr. Andrew MacFarlane of Albany said that as a result of the war all of the medical officers had felt that they should give part of their time to the nation and to the world. An idea had occurred to him personally, which might lead to something. Sickness was an expensive thing, especially to the poor man. Perhaps the net earnings of a family were $25 a week. When sickness came they had to call in a doctor to whom they could only afford to pay one dollar for a call. The fact was that they got one dollar's worth of service, when perhaps they needed five, ten, or twenty dollars' worth of service. Many country physicians had no opportunity to keep up with the modern laboratory methods; if he had the opportunity, through the State Board of Health, of calling on an expert for help and advice he himself would be improved in his efficiency and the family would get the needed advice without any tendency to pauperize them. This plan would be better for the patient and better for the medical practitioner.

Dr. Kidder of Oswego, N. Y., said that every physician should think very seriously of the ideas presented that day. About 40 per cent. of drafted men had been rejected and more sorrow and grief had been caused by exclusion from service than any other factor. One hundred and fifty years ago many people did not know how to read. To-day the need of education for everybody was realized and an admirable school system was taken as a matter of course. To-day the public were unconscious of the fact that a few years later they would be demanding the privileges of health for their sons and daughters, just as a few years ago they had demanded those of education. The fact that health insurance would obstruct rather than further that development was one of the greatest arguments that could be offered against it.

Dr. Wadsworth, in closing the discussion, said that as yet no health insurance had been put into operation that had been found satisfactory; whether any way could be devised in the future by which it could be made of value he did not know. As developed in England and Germany it was a signal failure. It had not provided what it proposed to provide and thus had been merely masquerading as a public benefit. He felt that Dr. Stockton had used the word "control" more than was perhaps advisable. There was little gained by attempts to control the people, unless they were educated to a clear understanding of the purpose of the work. This was more particularly true in infectious diseases, where regulation and control were so important. In the future of preventive medicine, control would be of even less importance, but development along the lines of practical service to physicians, of cooperation of State and local service, would be the most effective means of approaching these problems. Another question would be the development of federal health service in cooperation with State service. The federal service could supplement many departments of health which were not fully organized, but at present federal officials had to be more or less invited to do work in the various States, so that it had yet to be worked out how these two forces could cooperate to the best advantage in the future.

(To be continued.)

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

LOBAR PNEUMONIA.

A YEAR'S EXPERIENCE IN THE PRESBYTERIAN HOSPITAL WITH SPECIAL REFERENCE TO THE USE OF ANTIPNEUMOCOCCUS SERUM.*

BY T. STUART HART, M.A., M.D.,

NEW YORK.

VISITING PHYSICIAN TO THE PRESBYTERIAN HOSPITAL.

DURING the year ending July, 1918, there were discharged from the adult medical service of the Presbyterian Hospital with the diagnosis of *lobar pneumania*, 121 individuals. Preceding this period the plan had been formulated by the medical staff to make a careful study of the use of antipneumococcus serum in accordance with the methods introduced by Dr. Rufus Cole of the Rockefeller Institute. The first essential for such a procedure was the organization of the bacteriological department in such a manner that studies of the blood and sputum of all patients suffering from pneumonia should be carefully made and promptly reported. Such an organization was effected under the direction of Dr. W. W. Palmer and whatever value the studies may have is due to the energy and efficiency of the laboratories and the enthusiastic cooperation of the resident staff. Only those cases are included in this report in which the pneumonia was regarded as the primary disease, complicating and terminal pneumonias have been excluded.

TABLE I.

Group.	No. of Cases.	Identified by		
		Blood Culture.	Sputum.	Autopsy.
I	33	19	31	..
II	15	9	14	..
II, atypical	15	3	14	1
III	10	4	9	1
IV	23	3	23	..
Total groups	96	38	91	2
Miscellaneous	25	2	14	..
Total	121	40	105	2

In every case at least one blood culture was taken; in a number of cases as many as eight or nine cultures were studied. There was a total of 239 cultures taken in the 121 cases. A positive blood culture was obtained in 40 cases. The sputum was studied in every case in which a suitable specimen could be secured. On several occasions the classification was determined only by post-mortem cultures. As a result of these examinations the cases were classified in the following groups: (Table I.) The miscellaneous group included those showing as the predominant organism—*B. influenza* (4 cases), *B. mucosus capsulatus* (2 cases), *Staphylococcus aureus* (1 case), *Streptococcus hæmolyticus* (5 cases), and others in which for various reasons the predominant organism was not satisfactorily identified (12 cases).

*Read before the New York Society of Internal Medicine.

TABLE II.—MORTALITY.

Group.	No. of Cases.	Recovered.	Fatal.
I	33*	24	8
II	30	17	13
III	10	4	6
IV	23	16	7
Miscellaneous	25	18	7
Total	121	79	41

*One case left hospital—outcome unknown.

Mortality.—In Table II will be found the outcome in the cases of this series. The patients were admitted to the hospital in all stages of the disease, many in a moribund condition, others had serious complications which accounted for the fatal termination. No attempt had been made to segregate those presenting these serious features, except in those treated with serum which will be discussed later.

TABLE III.

Group.	Cases Showing Positive Blood Culture.				Fatal Cases.		
	Total.	Died.	Recovered.	Unknown.	Total.	Positive Culture	Negative† Culture
I	19	6	12	1	8	6	2
II	12	9	3	..	13	9	4

Miscellaneous	2	2	0	..	7	2	5
Total	40	23	16	1	41	23	17

*One case no culture made.
†In 14 of these cases only one attempt at a blood culture was made.

The relative mortality in the several groups follows much the same order as that reported by Dr. Cole. The very high mortality in those in which the pneumococcus III is the predominant organism is particularly noticeable. The finding of organisms in the blood stream would seem to indicate a severe course and a high mortality. Positive cultures were obtained in 40 cases. The clinical impres-

sion of the course of these cases classified them as follows: Severe 32, medium 5, and mild 3. Of these 40 cases 23 died, 16 recovered, and the outcome of one case is unknown, as the patient was removed from the hospital before the termination of the disease, and lost sight of. Of the 41 fatal cases 23 showed a positive blood culture, from the remainder no growth was secured from the blood stream; in one of these no culture was taken and in 14 only a single culture. It is possible that repeated examinations might have increased the number of positive findings. An analysis by groups of the outcome of these showing a bacteriemia is shown in Table III.

Group I.—Our observations were made on 33 cases. The intention was to treat every case with serum as soon as it was definitely decided that it belonged to this group, without regard to the day of the disease or the apparent severity. Under these conditions 31 cases received one or more intravenous injections of serum. One case died before the grouping was definitely settled, another had so far recovered when her group was determined that there was no object in serum administration.

Our method of administration followed as exactly as possible the rules laid down by the Rockefeller investigators.* From every patient showing on admission physical signs of pneumonia a blood culture was immediately secured and when possible a specimen of sputum. At the same time the sensitiveness to foreign proteid was determined by the intradermal injection of 0.02 c.c. of sterile horse serum diluted with 9 parts of normal salt solution. If the patient showed signs of sensitization he was desensitized by subcutaneous injections of serum in the usual manner. As a result of these precautions two patients were found highly sensitive to horse serum; they were desensitized and showed no further reactions at the time of the administration of the therapeutic doses.

A positive diagnosis of the group was obtained in 8 hours in several cases; in others it was delayed by the impossibility of obtaining a suitable specimen of sputum. This made it possible to administer serum to six cases within 12 hours after admission and to 19 cases within 24 hours after admission. The remainder of the group received their initial dose of serum more than 24 hours after admission.

Dosage.—An initial dose of 90 or 100 c.c. of serum was given. If at succeeding eight hour periods the temperature remained above 102° a like amount of serum was administered. A single dose of 100 c.c. was given in two cases and serum was then discontinued on account of the fall in temperature. In four instances a total amount of 1,000 c.c. was given to each patient; in three of these it was then discontinued on account of the fall in temperature. These patients recovered. The fourth patient showed no benefit and the administration was therefore stopped; he died some days later. The serum employed was for the most part furnished us through the courtesy of the Rockefeller Institute. In a few instances serum provided by the New York Board of Health was used.

*Avery, Chickering, Cole & Dochez: "Acute Lobar Pneumonia," Monographs of the Rockefeller Institute for Medical Research, No. 7, 1917.

Reactions.—Early reactions occurred in 15 cases immediately following the first dose of serum; of these 7 were very insignificant, consisting of a few urticarial wheals with a mild degree of accelerated breathing; in 8 cases the symptoms were more pronounced extensive urticaria, dyspnea, cyanosis, acceleration of the pulse, sometimes cough, vomiting, and headache. In none of these were the manifestations alarming, and they were at once relieved by the administration of adrenalin.

Thermal reactions with rise in temperature with or without a chill were noted in 6 instances. These followed the administration of the first dose of serum in 4 cases; in one case after the fifth dose, in another after the seventh dose.

Late reactions appeared in all but two cases who lived long enough to allow these to develop. They were classified as mild 10, medium 6, severe 9. These reactions usually appeared on the sixth or seventh day after the initial therapeutic injection of serum. In one instance the onset was on the third day, and in another case on the eleventh day after the first dose of serum. The duration of the symptoms of the "serum sickness" was very variable; in some it was terminated in two days; in several disturbances were evident for a full three weeks. A glance at the tabulation of these cases (Tables V and VI) indicates at once that there was no definite relation between the amount of serum administered and the severity of the reaction; several cases receiving 1,000 c.c. of serum showed only the mildest reactions, while severe reactions were often encountered in those who received very few doses.

A mild reaction often consisted of a few patches of urticaria and a moderate enlargement of the superficial lymph nodes. In the severe reactions there was pronounced and prolonged urticaria often with extensive erythema, fever, marked enlargement of the lymph nodes, a moderate eosinophilia, subcutaneous edema and inflammation of the joints. In several instances the patient's condition simulated an attack of acute rheumatic fever. The joints of all of the extremities were swollen, hot, red, and exquisitely sensitive to the slightest touch or movement. Some of these patients appeared very ill for a few days, but all made a complete recovery. Two cases showed as the most distinctive feature of their reaction a general scarlatiniform erythema covering the whole body, head, trunk, and extremities. Both of these subsequently exhibited a coarse desquamation during which the skin was shed in large flakes.

A type of reaction which caused us considerable concern and which was seen in a number of patients consisted of prolonged, irregular fever reaching 101° or 102° and lasting for one to three weeks, several of these presented physical signs suggestive of fluid in the pleura. The probability of empyema in these cases seemed very strong and they were repeatedly examined with the *x*-ray and often explored with a needle, but subsequently cleared up, leaving us to conclude that the serum reaction alone accounted for the fever. While patients with severe reactions with arthritis and prolonged fever often appeared to be very ill they all sooner or later cleared up and there appears to be no danger to life in any of these cases of serum sickness.

Sterilization of the Blood.—One of the strongest

arguments for the use of antipneumococcus serum has been its experimentally demonstrated power to render sterile the blood stream of animals infected with the pneumococcus. It seems therefore of value to examine the fragments of clinical evidence which our small group of cases presents to obtain if possible some light on the effect of serum on the bacteriemia.

Positive blood cultures were secured in 19 of the 33 cases comprising Group 1. In 13 cases a sufficient number of cultures were taken to allow us to formulate our impressions in regard to the effect of serum in sterilizing the blood. In five instances the blood which had showed a growth just before the administration of serum became sterile after the first or second dose and remained sterile thereafter. Of these cases two deserve special mention. No. 37075 entered the hospital on the 5th day of his disease, showing an involvement of the whole right lung. The admission blood cultures showed 154 colonies to 1 c.c. of blood. The blood cultures taken a few hours after the first dose of serum showed no growth and this was confirmed by four subsequent cultures. No. 37461 showed perhaps the most extraordinary improvement in this respect. The initial culture showed 3 colonies to 1 c.c. of blood; 24 hours later the culture taken just before the first administration of serum showed 940 colonies. Four subsequent blood cultures following the administration of serum showed a blood stream absolutely sterile. Evidence of this kind appears to be very striking. On the other hand the power of the tissues to develop a spontaneous immunity must not be forgotten. In three instances in which the admission culture gave a positive growth of pneumococci, the second culture taken just before the administration of serum showed a sterile blood and no further growth could be secured during the course of the disease. All three cases recovered. None of these cases showed, however, the high bacterial content which was found in the two cases already cited. The highest of these cases showed only 10 colonies to 1 c.c. of blood.

In this connection mention should be made of several other cases which were somewhat irregular in their manifestations. No. 36661 showed a positive growth from the blood before and after the first dose of serum. Following the second dose of serum the blood stream became sterile; 7 days later an empyema was discovered and pneumococcus I was recovered from the pleural exudate. At this time the blood stream again showed a growth. This case terminated fatally. No. 37013 entered the hospital on the 5th day of his disease with consolidation of the right upper and middle lobes. A positive culture was obtained from the blood. He was given 3 intravenous injections of serum. The blood became sterile and recovery seemed assured. Temperature was normal for 9 days. It then began to rise and the physical signs pointed to a reinfection of the lung at the site of the initial lesion. At this time the blood again showed the presence of pneumococci and this continued in spite of the administration of serum until death, which occurred 5 days later. At the post mortem there was found an acute pneumococcus endocarditis. No. 36934 showed in his admission culture on the 5th day of his disease 33 colonies to 1 c.c. of blood. In spite of the administration of 1,000 c.c. of serum the temperature never became normal and repeated blood cultures showed pneumococcus present up to the time of his death, which occurred on the 19th day of his disease. The post mortem showed an acute pneumococcus endocarditis with fresh vegetations of the mitral valve. No. 37109 was admitted on the 10th day of her disease with consolidation of the left lower lobe. The initial blood culture showed 31 colonies to 1 c.c. of blood, and in spite of the administration of 1,000 c.c. of serum the temperature never became normal and the blood continued to show pneumococci in considerable numbers up to the time at which she left the hospital against advice, which was 26 days after her admission. While she was in the hospital she developed a distinct systolic murmur and it was suspected that she might have an acute endocarditis. The patient could not be traced and the outcome is unknown, but one would fear a fatal issue.

While the evidence here presented is decidedly fragmentary it seems to us to indicate that the administration of serum affords a definite aid to nature's effort to sterilize the blood stream. The failures which are recorded are very instructive. In each case there was a localized focus of infection which continued to furnish pneumococci to the blood stream. In one instance this was an empyema; in three others an acute endocarditis was present, and in two of these, which were examined post-mortem, there were found on the heart valves fresh vegetations containing pneumococci.

		Crisis.	Lysis Began.
2	2nd day	3, 4	.....
2	3rd day	3	4
8	4th day	4, 5	4 [2], 5 [4]
4	5th day	6 [2], 7	5
4	6th day	6, 7	6, 7
2	7th day	7	7
1	8th day	11	.....

Figures indicate day of disease. Figures in brackets number of cases.

Course.—There was clinical or post-mortem evidence of the involvement of more than one lobe in all but one of the fatal cases. In those that recovered 6 showed physical signs of consolidation of two or more lobes. The general clinical impression classified the severity of the course of the cases which recovered and which received serum as follows: Mild 8; medium 7; severe 8. Table IV shows the progress of this same group of cases and the manner of defervescence.

One should be extremely cautious in drawing conclusions as to the effect of serum in modifying the course, from such figures as the above table presents without a corresponding group of controls in which serum had not been employed. Such a series we cannot present. We may say, however, that the apparent improvement associated with the administration of serum is most marked in those who received it early in the course of the disease. Furthermore the termination by crisis on or before the fifth day in 5 cases and a gradual fall of tempera-

ture beginning on or before the fifth day is certainly very impressive. The extraordinary and prompt improvement which occurred following the administration of serum in several instances cannot be duplicated in our clinical experience with lobar pneumonia.

Fatal Cases Treated With Serum.—Throughout this paper we have studiously avoided the recording of our results in percentages. We have done this since we believe that conclusions based on the statistics of such a small number of cases are very misleading. The position is reinforced when we examine individually the 7 cases of Group 1, which were treated with serum and terminated fatally.

Reference to Table VI will indicate the serious nature of the complications in these cases and em-

phasizes the limitations of serum in combating focal lesions.

Two cases each admitted on the fifth day of the disease, each extremely ill, each with a complicating pericarditis, died within 24 hours after admission. Each of these patients received two doses of serum, but without apparent effect.

Case 36661 received his first serum on the fourth day of his disease. After the second dose the blood stream apparently became sterile. On the 10th day of the disease the blood again showed a growth of pneumococci, empyema appeared, and a rib was resected. He died on the 12th day of his disease.

Case 37567 received his first serum on the sixth day of his disease. He apparently did well and the crisis occurred on the seventh day. After five days of normal temperature, then signs of meningitis developed, from which he died on the 28th day of his disease. The day before death a hemolytic streptococcus was recovered from the blood. In this case the pneumococcus was probably not the cause of the meningitis.

Two other fatal cases (36934 and 37013) have already been cited in discussing the effect of serum in sterilizing the blood stream. It was pointed out that in both instances the difficulty in securing a sterile blood was due to the fact that fresh vegetations on the heart valves were continuously supplying pneumococci to the blood. One of these cases was further complicated by an abscess of the lung, the other by a meningitis. From the spinal fluid the pneumococcus was recovered in pure culture.

It is evident that in nearly every case of this series death was due to some lesion other than the pneumonia. The administration of serum appeared to have little or no influence on these complications when once established. Would the earlier administration of serum have prevented the development of these complications? Our present evidence gives us no answer to this question.

Résumé.—1. A positive blood culture in lobar pneumonia is usually an indication that one may expect a severe course.

2. It is rare for a patient who has received serum to escape a subsequent "serum illness." This may be mild or severe, but bears no relationship to the amount of serum given. Serum illness in these cases does not endanger life.

3. Antipneumococcus serum is a distinct aid to nature's effort to sterilize the blood stream.

4 When serum fails to sterilize the blood an acute pneumococcus endocarditis should be considered as a possible cause. This was present in three of our cases.

160 West Fifty-ninth Street.

Hereditary Immunity Against Rabies.—Remlinger denies the existence of this laboratory phenomenon in the rabbit. In an artificially refractory female he found that the offspring could all be inoculated successfully under the dura and showed no immunity in inoculations elsewhere. Such immunity as does develop is so slight and so irregular as to be negligible.—*Gazette des hôpitaux.*

IDEALISM IN RHINOPLASTIC SURGERY.

By WILLIAM WESLEY CARTER, A.M., M.D., F.A.C.S.,

NEW YORK.

THE idealist is a star-gazer, and his is a fixed star, it is individual, it is personal. The vision of others may be directed toward the same star, but the line of vision is always from a different angle, and individual efforts to attain to this ideal differ as widely as material objects differ from each other physically and otherwise in the realm of the material. When one presumes, therefore, to discuss idealism in any field of effort his views must be accepted as individual and as acquired by contemplating the object of his ambition from his own point of view, *his angle*. Writers upon either medical or surgical subjects are frequently so strongly imbued with the idea that something new in the way of treatment or technique must be advanced, in order to justify the effort, that the good, practical, tried out, firmly established principles, upon which we rely in our daily practice and upon which our patients are dependent for relief, are so disregarded or camouflaged, to use an up to date and very expressive term, by the novelties introduced under these compelling circumstances that one must be safeguarded by a wide clinical experience, a well developed sense of discrimination and an unusual amount of common sense in order not to be diverted from paths, the comparative safety and approximate efficiency of which are known. Attention is called to this matter, not in a spirit of criticism directed toward those who are responsible for this condition of affairs, for we recognize that the fault lies in the uncontrolled enthusiasm and zeal of progressive, aggressive members of the profession who are trying their best to reduce the practice of medicine and surgery to as near an exact science as the nature of this work will admit. But we would call attention to the fact that if we are to avoid many of the mistakes that are made in our desire to increase the scope and efficiency of our efforts and incidentally to spread the knowledge of our existence, we must keep constantly in our mind, and be guided in our efforts by the physiological laws which govern all of the functions of the human body and control the delicate metabolic and nutritional changes which occur in the tissues, and realize that these laws are fundamental, are established by Nature, and are not to be tampered with, modified, or ignored by any man no matter how learned and self-confident he may be. To none do the above remarks apply more forcibly than to the metropolitan practitioners and to those who enjoy the educational, laboratory, and clinical advantages to be found only in our large centers of population. There rests upon these men a heavy moral responsibility to fellow practitioners less advantageously placed in smaller places all over the country. This responsibility cannot be shirked, it must be faced and its paramount importance must be realized, especially by those whose observations find an outlet through literary channels.

It is natural and proper that the opinions of those who are so situated that they can command a large amount of clinical material should be respected; on the other hand this confidence should be held by those in whom it is reposed as a sacred trust the violation of which may indirectly cause untold expense, suffering and disappointment, especially among the thousands of patients of the extraurban physicians who have relied upon the accuracy of the clinical observations made by those of us who are supposed to have passed judgment upon our recommendations only after reliable clinical tests have been applied. There are often exploited in our medical journals methods of medical and surgical treatment the practical value of which has not been proved clinically, and the splendid results recorded have not in many instances been subjected to the most important ordeal of all, the impartial test of time. For this reason when I was chairman of the Laryngological Section of the New York Academy of Medicine, I had printed on the program of each meeting the following notice: "Patients presented before this section may be recalled at a subsequent meeting by notifying the Secretary."

Let us apply the above observations to the branch of rhinological surgery having to do with that class of depressed nasal deformities due to the destruction of the bony and cartilaginous framework and commonly known as saddle-back nose. I have devoted many years of careful study to this subject, striving to perfect a method for reconstructing these organs in a physiological manner. I began this work nearly fifteen years ago, my attention being directed to these patients chiefly by the fact that up to this time little or nothing had been done to relieve these unfortunates and certainly no method had been devised which was based upon scientific principles, which complied with the physiology of the human body and which produced permanently satisfactory results. The mechanical conditions met with in this class of deformities may be compared to a roof without supporting rafters. In this deformity there is a definite deficiency, due to disease or injury, in the rigid framework material; the latter is just as important and essential to the construction and support of a nasal bridge as it is to the roof of a house. Therefore deformities of this class cannot possibly be corrected without supplying this deficiency; this is a basic requirement. For many years past various operators, some of them possessing the highest degree of skill, have from time to time attempted to supply this deficiency and support the nasal bridge by introducing various foreign materials shaped to suit the deformity, such as guttapercha, celluloid, etc. Invariably these materials sloughed out and the deformity was worse than it was before the operation and the prospects for ultimately correcting it by rational means were immeasurably reduced. And why should this not be the result? Even a cursory review of the physiology of the situation will answer the question. We grant that almost any foreign body, chemically neutral to the tissues and fluids of the body, can be made to heal in, provided that it is aseptically introduced and it will remain indefinitely provided that the patient maintains a condition of perfect health, that he does not grow

old, and his tissues do not undergo the natural atrophy of advancing age, and provided that the foreign body has no resistance to overcome, in other words that it accomplishes nothing. These postulates are self-evident and must be accepted; their acceptance means an admission that nasal deformities cannot be corrected permanently by the introduction into the tissues of foreign material of any kind. If the foreign material is introduced skillfully it will reduce the deformity and it may remain in the tissues long enough for photographs to be taken showing the wonders performed, but, alas! history will repeat itself, it will surely slough out. At those points where the material, whether it be rubber, celluloid, or what not, exerts pressure in lifting up the sunken bridge, there is a thin layer of tissue in immediate contact with the material which is deprived of its blood supply, there is, therefore, a progressive necrosis going on at this point, the overlying tissues become thinner and thinner until the foreign body is expelled. Truly Nature abhors the presence in the living tissues of a foreign body, whether that body be artificially introduced or whether it be some part of the body, bone or flesh that has ceased to live. On the other hand I have shown by a large number of cases operated upon over a period of nearly fifteen years that an autogenous bone and cartilage transplant properly introduced fulfils perfectly the indications in these cases and that it lives and grows. *X*-ray examinations, which have been made at intervals in some of my oldest cases, show that the growth of the bone is regulated by the functional demands of the part—there is no overgrowth in any of my cases. In many instances it is necessary to supplement the bone transplantation by shifting the tissues subcutaneously and occasionally by turning flaps.

We may refer to the procedure I have here outlined as being strictly a physiological method for correcting nasal deformities of this class, for only tissues normal to the body are used, their vitality is unimpaired, and not only the shape and proportions but the normal structure of the nose is reestablished. If the ideal in surgery, namely the restoration to normal of an abnormal part can be secured by only one method, and this method has been thoroughly tested on a large number of cases and the results secured have been submitted to the most impartial of all tests, that of time, then what ground is there for the exploitation of the theory that these results can be accomplished by the introduction of foreign bodies into the tissues, a procedure which it is well known is against the physiological laws which govern the vital processes in the body.

In conclusion I will say in the light of the experience I have gained in operating upon large numbers of these patients that there is no method comparable to that of bone transplantation in the class of cases under discussion, but this must be supplemented in many instances by the shifting of the tissues subcutaneously in order to fill in irregularities and perfect the basic results secured by the implantation of bone.

In regard to the permanency of the results, I may add that the present condition of my oldest cases, those of twelve years standing, shows that this method has stood the test of time, for the correction remains as it was immediately after the operation.

THE ETIOLOGY OF THROMBO-ANGIITIS OBLITERANS.

By WILLY MEYER, M.D.,

NEW YORK.

ATTENDING SURGEON TO THE LENOX HILL AND POST-GRADUATE HOSPITALS.

Further study and observation of patients suffering from so-called thrombo-angiitis obliterans have gradually led me to the conviction that this trouble is a systemic disease and not, as Buerger believes, a primary affection of the blood vessels.

There seems to be *just one* etiological factor responsible for the characteristic syndrome: claudication, pains, gangrene, and this I believe to be: tobacco-smoke poisoning.

While it is true that this factor also influences the blood vessels, still their pathological changes appear to me secondary, and therefore not the original cause of the phenomena.

The combined effects of the nicotine, pyridine, cyanic hydrogen, carbon monoxide, and other poisons contained in the smoke of tobacco are responsible, I believe, for all the characteristic clinical manifestations of the disease. The onset of these symptoms heralds the complete saturation of the patient's system with tobacco-smoke poisons.

In other words, I consider the so-called thrombo-angiitis obliterans the final stage of cigarette-smoke poisoning in a certain type of individuals under certain well-defined conditions.

I had intended to discuss these views in detail in a paper to be read before the coming meeting of the American Medical Association, but have been informed by the Program Committee that it has been decided to devote the entire meeting of the Surgical Section to War Surgery.

While there will, no doubt, be a chance to present the paper in the fall, the principal deduction from the above stated conclusions, if correct, is perhaps of sufficient practical value to warrant its publication at this time.

The male Hebrew immigrants from the southeastern part of Europe, who are the principal sufferers from this disease, should be advised to *quit smoking!*—not merely reduce it, but stop it entirely. Even so, there is at the present stage of our knowledge hardly a cure for the majority of these cases. Once the system has become thoroughly saturated with the toxic agents, mere abstinence no longer avails. The cure of the trouble for the present should be, so to speak, rather prophylactic. The young men of the class of people in question should be warned in good season—at home, in school, from the pulpit—of the deleterious effects and serious consequences to them of the excessive use of cigarettes. Otherwise, many of them may find themselves incapacitated for work at a comparatively young age, and unable to earn a living—a pretty high price to pay for an acquired taste!

700 Madison Avenue.

A CASE OF ATYPICAL MALE SEX ENSEMBLE.

By ARTHUR STEIN, M.D., F.A.C.S.,

NEW YORK.

ASSOCIATE GYNECOLOGIST, LENOX HILL AND HARLEM HOSPITALS.

MALFORMATIONS of the sex apparatus in which both the male and female sex glands are present are very rare and the few available observations concern the histological demonstration of testicular and ovarian tissue rather than the existence of bisexual functionating glands. More common abnormal sex conditions formerly described as "pseudo-hermaphroditism" represent either an atypical male sex ensemble or an atypical female sex ensemble, a term

FIG. 1.—Full view of subject.

recently suggested by Hart as an improvement on the older and not strictly correct designation.

In the cases of atypical male sex ensemble the presence of a more or less normal vulva is simulated by penoscrotal hypospadias with more or less rudimentary development of the hypospadic penis. The new-born child in many such cases is unhesitatingly considered a girl. As a rule there is hypospadias of the penis alone, sometimes with partial division of the scrotum, the upper half of which contains the urethral orifice. In other cases the scrotum is completely divided. Sometimes the borders of the split penile urethra simulate rudimentary labia minora. The apparent clitoris may be enlarged, but is occasionally rudimentary as compared to its normal size. In exceptional cases the penis may present a normal structure while the scrotum is alone divided in its lower portion, where a vaginal opening is occasionally demonstrable.

A case of atypical male sex ensemble recently came under our observation, and although not an example of the most unusual variety, appears sufficiently interesting to justify its publication:

E. M.—Came to the Harlem Hospital of New York City with the following history: Thirty-one years of age. She was born and brought up in Finland and has never menstruated. Her occupation has been that of a servant; for the past three years she has been employed in the same family as cook. She knows that there is something wrong with her genitals and the desire to marry is now bringing her to the hospital in order that she may be made a normal woman. Although she has never menstruated, she thinks that she has pains in the lower abdomen every four weeks. She states that she has never been attracted to women, but only to men, and desires to marry the butler employed in the same household. The patient has always had sexual feelings toward men, although she claims that on erection the penis is about 1½ inches long. At the end of the orgasm an emission rarely occurs.

Two and a half years ago the patient was operated upon for appendicitis at the Harlem Hospital by Dr. Luckett. Through an enlarged incision it was shown that no uterus, tubes, or ovaries were present. In fact, no female genitals whatever. The pelvis was that of a normal male. (No mention was made of seminal vesicles.)

Family History.—Mother an unusually large woman; father also very large. Parents had twelve children; eight are living. One brother abnormally built, penis being very small. One abnormally built sister. Cannot describe her sexual abnormality.

General Description.—Height, 5 feet 6 inches. Voice that of a female contralto. General appearance that of a strong, well-built woman. The bones of the head are well developed and very pronounced, as in the Mongolian type. Pomum Adami not pronounced. The hands and arms are extremely long and large and are partly covered with hair. The thorax is entirely male in type. The breasts are perfectly flat as in the male. Legs are covered with hair as in the male. No adipose tissue is present as would be expected in the female. All the muscles of the arms and legs are well developed. The hair line of the pubis is that of a female.

Pelvic Measurements.	*Pelvic Outlet Measurements.*
Dist. Interspinal, 28 cm.	
Dist. Intercristal, 29 cm.	Dist. Antero-post., 4 cm.
Dist. Trochanter, 32.5 cm.	Dist. Transverse, 5.5 cm.
Dist. Ext. Conjugate, 20 cm.	Height of Perineum, 9.5 cm.

Local Examination.—In the region of the left external inguinal ring there is a slight protuberance which on examination proves to be a mass about the size and shape of an olive, movable into the left "labium majus." The mass is somewhat tender on pressure. The right "labium majus" is much larger than normally and contains an olive-shaped mass which is movable and which is somewhat larger than the left tumor. The surfaces are those of a normal testicle and epididymis, and the spermatic cord can be easily felt. In place of the clitoris there is an organ which in its entire make-up resembles a penis of the new-born type. At rest it is 4 cm. long (1½ inches). The prepuce is well formed. The glans penis shows no opening. The urethral opening, however, is to be found at the root of the penis on its posterior surface as a very small pinhead-like opening. No vagina is present; in its place the perineum is found to stretch from anus to root of penis, forming a firm raphé between the two "labia." Upon rectal examination no prostate was found.

Diagnosis.—A typical male sex ensemble (pseudo-hermaphrodite of male type).
Rudimentary penis.
Hypospadias.
Undescended testicle on left side.

Descended testicle on right side.
No internal female genitals present (as shown in previous laparotomy).
Absence of prostate gland.

In this case it was not considered advisable to perform any operation either of forming a vagina or fixing

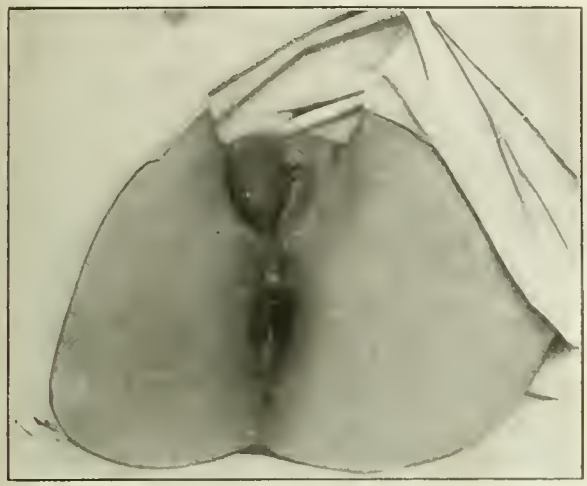

Fig. 2.—Showing the olive-shaped body in the left labium majus.

the testicle on the left side, as the patient felt perfectly well and only her desire to lead a woman's life brought her to our attention.

A case resembling ours in many details was described by König in 1907 in a letter addressed to Neugebauer. It concerned a servant girl of twenty-five years who had never menstruated and finally consulted a gynecologist to learn the reason. She was told that she had not the right to become a wife, but objected on account of her engagement to a young man who was determined to marry her. Another gynecological examination later on showed the case to be one of true atypical male sex ensemble. On the basis of various considerations it was decided to leave the patient in ignorance as to her real sex, for she would have been unable to earn a living as a man, whereas she managed very well as a woman.

Another representative of this group observed by Neugebauer was a cook of twenty-six years who fully dressed appeared like a well-sized, full-bosomed and long-haired woman with feminine features. She had no mammary glands, however, their presence being merely simulated by the abundant subcutaneous fat which was distributed over the entire body. The voice was deep, but not decidedly masculine. The pubic hair was scanty and of feminine type. The shoulders were broader than the pelvis. On separating the thighs the picture of penoscrotal hypospadias was revealed. An operation was performed and showed left-sided cryptorchidism. There was neither a uterus nor a vagina. The prostate gland was likewise absent. In this instance the subject, apparently a woman, was officially declared to be a male in conformity with her physical constitution.

Still another case, also reported by Neugebauer, was that of a girl twenty-one years of age who had never menstruated and who had been jilted by her fiancé when he was informed that the marriage would be childless on account of her abnormal sex apparatus. The girl demanded an operation in order to be made a normal woman and insisted that she would sooner die than remain unmarried. Her breasts were female and decidedly large. The shoulders were broader than the pelvis. The pubic hair was of the male type. On separation of the thighs and labia a small penis was exposed and palpation readily demonstrated a testicle with epididymis and spermatic cord on each side. There also seemed to be a rudimentary vagina, but no uterus or prostate was found on rectal examination, which, however, plainly revealed the presence of the two vasa deferentia.

A case of atypical sex ensemble reported by Goltman in Canada concerned a supposed male subject of 28 years who was described and pictured as of magnificent muscular and skeleton proportions; in the nude condition especially he could easily have passed as a woman. Description: "The face is absolutely beardless; no hair in the axillæ or any other part of the body excepting the scalp and the few comprising the mons veneris. The skin over the entire body is soft and white like a woman's. . . . His voice is high-pitched, soft, and musical. . . . There are two well developed mammary glands; the nipples are prominent, capable of erection and surrounded by well marked areola with papillæ devoid of hair. The pubic region is covered with a small amount of feminine hair and below it in the erect position are seen three prominences, imperforate penis, 1½ inches long, capable of semi-erection; right testicle; left testicle. In the lithotomy position the scrotum is seen to be divided. She urinates in the squatting position. Examination per rectum reveals absence of prostate gland, absence of uterus and ovaries. The pelvis and thighs are of the masculine order, but not markedly so, and the pubis is cushioned with adipose tissue." The sex was doubtful in the opinion of the observer, who was inclined to class this subject as being of the neuter sex until postmortem evidence proved differently. In the light of recent political developments it is amusing to note the parting shaft with which Goltman concludes his article in the words: "It has never voted."

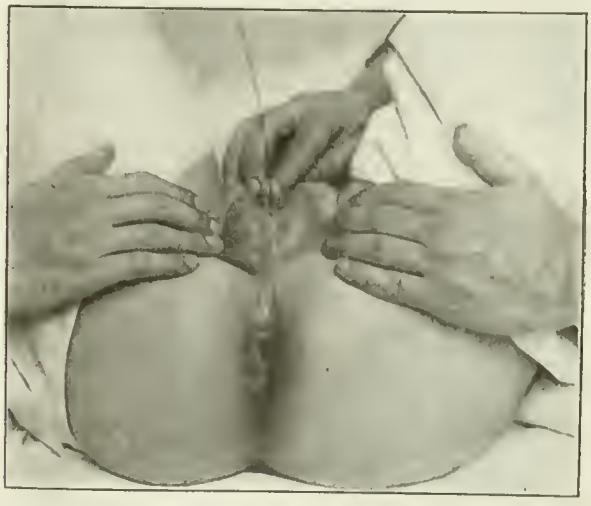

Fig. 3.—Showing a catheter in the urethra.

A case of atypical female sex ensemble in a boy of eleven years showing unusual accentuation of the secondary sex characteristics of the male was recently reported by Quinby from the Brady Uro-

logical Institute of the Johns Hopkins Hospital. An operation was performed in order to correct the hypospadice condition and to search for the supposed testicles, but no trace of the spermatic cord could be discovered in the inguinal canal. On entering the abdomen, however, the operator found an infantile uterus with tubes and ovaries of normal appearance. These findings in conjunction with the result of microscopical examination plainly showed that this patient belonged to the type of atypical female ensemble.

Walther's observation of a boy 19 years of age is probably unique because characterized by the combination of the distinctive features of *both sexes* in the same individual with perfect parallel development of the two halves of the external genital apparatus according to the two types, as well as perfect development of the external apparatus according to the male type.

Here at the present state of our embryological and morphological knowledge the various malformations representing atypical sex conditions are fairly well understood, although it still remains an open question why in one case the sex glands will develop in the male and in another in the female direction. It is equally unsettled why in other cases the development is arrested at such a rudimentary stage that the genitals acquire no definite sex characteristics.

The psychic sex attitude of these individuals is extremely variable, from practically normal to absent, or perverse and homosexual. Although from one viewpoint the sex of an individual is decided by the anatomical character of the sex gland, the development of the psychosexual center is given an extremely wide scope through education, example, and suggestion, so that as a rule the psychosexual sensation of atypical persons are largely dependent upon their early environment. In the author's case, for instance, the patient's bringing up as a girl was probably chiefly responsible for the real or imaginary experiencing of female sexual desire for the male, namely, homosexual manifestations. Presumably, as in many cases of this kind, the psychosexual susceptibility was more or less dulled and absent, the intended matrimonial venture being essentially one based on purely commercial considerations.

Medical and Surgical Lessons of the War.

WAR LESIONS OF PERIPHERAL NERVES.

By J. LE FLEMING BURROW, M.B. (Edin.); M.R.C.P. (Lond.).

Leeds, England.

Captain R. A. M. C. (T. F.) Officer in Charge of the Neurological Department, Second Northern General Hospital, Leeds.

Introductory.—This paper is based upon the experience gained from over 15,000 routine investigations of war injuries to the nervous system during the years 1914-1915 and 1917-1919. The work has been carried out in the Second Northern General Hospital, Leeds; to the administrator of which, Lt. Col. Littlewood, I express grateful thanks for permission to publish this paper. The work of the hospital has been made possible only by the full cooperation of the medical and surgical staff, and by the loyal team work of assistants in the special departments. To my surgical colleagues especially, I am most deeply indebted; without their help my particular work could not have been done. The photographic records were made possible by the help of the Medical Research Committee.

The work of my department consists in the routine examination and recording of all cases where nerve injury is suspected. An opinion is expressed upon each case as to diagnosis and progress while under observation. The department is also jointly responsible with the surgeon for the after-treatment of the patient when nerve suture has been performed. It has been found a convenient working arrangement for the Neurological Department to prescribe and control the electrical treatment, etc.; in this way multiple control of a patient is obviated.

The surgical aspect of all cases is entirely in the hands of surgical colleagues. Treatment is decided upon after a consultation between officers of the surgical and neurological departments. One morning in each week is set apart for a meeting of the officers from all the departments of the hospital. At these meetings cases of special difficulty or interest are fully discussed, and advice from each department, if necessary, is available.

The following paper is intended to be a short, practical guide to the subject of nerve lesions in the light of our increased experience gained during the war. A detailed discussion of the facts which have come to light during research upon the motor and sensory functions of nerves is beyond the scope of the present article.

Anatomical and Pathological Types of Lesion.—A. Direct injury of a nerve trunk by a metal fragment may result in:

1. Complete division of the nerve.
2. Total division of a few bundles only in the nerve.
3. Injury to the sheath of the nerve, and its nutrient vessels and nervi nervorum.
4. Bruising and hemorrhage between the nerve bundles within the perineurium.

B. Indirect injury of nerves may result from:

1. Displaced fragments of bone, where there is a splintered fracture.

2. Pressure from without, due to organization into fibrous tissue of large blood clots, callus, etc.
3. Fibrosis and repair processes, following intense sepsis which has invaded the nerve from the neighbouring tissues.

CLINICAL AND PATHOLOGICAL RESULTS OF THE VARIOUS TYPES OF INJURY.—A. *Direct Injury of a Nerve Trunk.*

1. *Complete Division:* Direct and total division of a nerve trunk, and especially of a large nerve, such as the sciatic, by a bullet, is rare. If a bullet passes through a medium sized nerve, complete loss of function usually results at once. Many nerve bundles are directly divided and the others are bruised to such an extent that they cease to conduct impulses for a time.

Surgical exposure of the damaged nerve a few weeks later enables one to make out a dense fibrous swelling in the centre of the nerve trunk, and at each side of this a few fibers enter the young vascular scar tissue and become lost there. These latter fibres probably correspond to the bruised fibres, now entwined with scar tissue, while the central area marks the spot where the bundles have been cut across during the passage of the bullet.

The clean cut nerve wounds result almost exclusively from high velocity rifle and machine gun bullets. Shrapnel shell wounds and metal fragments cause much more laceration, and ultimately heal with dense fibrosis. Where the nerve has been completely divided and its ends are found separated by an interval, one sees that there is a bulbous swelling upon each end of the cut nerve. The swelling upon the proximal end is larger and usually softer to the touch than that attached to the peripheral cut end, which feels hard and compact. The signs and symptoms associated with this complete nerve division are discussed later in these pages.

2. *Total Division of a Few Fibers Only in a Nerve:* A glancing wound of a nerve trunk may make a clean cut at one side of the nerve only. In this case a few fibres are anatomically interrupted, those near are bruised and lose their conductivity, while those most distant may still conduct almost normally in a few days, or it may be, in a week.

Pathologically such a lesion usually results in the development of the commonly described "lateral neuroma". The appearance at the repair operation will vary according to the amount of the preceding suppuration, or the comparative absence of such sepsis. Young vascular fibrous tissue will be spread widely round the site of the injury after a few weeks of sepsis. In cases where the wounds heal quickly a sharply defined lateral swelling on the nerve will mark the track of the bullet. This swelling consists of fibrous tissue, varicose nerve fibrils, and the remains of the degenerated fibers cut at the moment of the injury.

On the uninjured side of the nerve, strands of healthy fibers will be seen passing over the swelling into the peripheral end to pass in the ordinary way to their distribution. It is almost needless to say that the changes found will vary much according to the interval which has elapsed between the date of injury and that of the operation to expose the nerve. The signs and symptoms of the incomplete lesions follow in later pages.

3. *Injury to the Sheath of a Nerve:* The injury to the coverings of nerve tissue proper, with outpouring of blood into the nerve, and subsequent fibrous transformation, is one of the most fruitful sources from which spring cases of "nerve concussion", less serious "partial lesions", and those distressing cases clinically called "Causalgia". The pathological changes may be little evident to the naked eye when the nerve is exposed at the operation.

The fibrous tissue is very limited in amount, and may merely lead to a diffuse local thickening and sclerosis in the nerve. On opening the sheath a few strands of young fibrous tissue will be seen to enter the nerve bundles, separating them, and causing a certain amount of torsion in their course. The local thickening in the sheath may be circumscribed and large enough to suggest the presence of a lateral traumatic fibroneuroma.

Clinically, in the early days after such an injury, there is usually some loss of function in the affected nerve.

For a few days the patient often notices a curious neuralgic pain, like a bruise, in the sensory distribution; there may be lack of motor power in the muscles supplied by the nearest efferent fibers. A week or two later this pain fades away and a "numbness" is left. The numb area is found to be hypoesthetic to all forms of sensory stimulation.

The further clinical history seems to depend upon whether there is much or little fibrous tissue developed at the site of the injury. If little fibrosis occur in the repair process, then the functions of the nerve, both afferent and efferent, are gradually restored.

In some cases fibrosis leads to the production of a syndrome of nerve irritation. The symptoms appear from the tenth to the fourteenth day after the injury, and may become gradually worse or gradually better, according to the severity of the damage at the site of the injury.

The clinical features of the syndrome of irritation are discussed amongst the clinical types.

4. *Bruising of Nerve Trunks:* The effusion of blood into the nerve bundles of a nerve trunk results from the passage of a bullet through tissues intimately associated with that structure. Damage may also result from such violence as the blow delivered by a man with a clubbed rifle, by the fall of sandbags, or other violence applied as a result of shell bursts. The carrying of heavy ammunition boxes on the shoulder has often caused bruising of the upper trunks of the brachial plexus, as the soldier stumbles over rough ground.

Clinically these cases come to us after shell explosions, etc., as cases of "nerve concussion". The damage may be so small that the symptoms pass away in a few days, and the soldier resumes duty.

A certain number of these cases do not clear up, and after a day or two of radiating pain, described as like a "deep bruise", along the nerves affected, there results a stage of "numbness".

The latter stage may pass into the clinical type known as a "partial lesion" of nerve, according to the number and distribution of the fibres damaged. On the other hand, in some nerves especially, such as the inner cord of the brachial plexus, the median nerve of the arm, or the internal popliteal division of the sciatic, a typical "causalgia" syndrome re-

sults. This syndrome is so striking that it is described fully in a separate section.

It should be emphasized that the "partial lesion" which results from intraneural hemorrhage is the commonest type of lesion to result in "causalgia" The burning pain is usually first noticed about ten days after the reception of the injury, and from that time it grows more intense. The exact pathological features of the early stages of this type of injury have not been much noticed.

I have been able to pick out a few cases sent back from casualty clearing stations with notes stating that there was bruising with hemorrhage into nerve sheaths, where the later result was "causalgia", or an irritation syndrome of less severity. Microscopically we are able to demonstrate intraneural fibrosis to quite a marked extent, where, to the naked eye, the nerve appeared very little changed at the operation.

B. *Indirect Injury to Nerve Trunks.*

1. *By Displaced Fragments of Bone:* Laceration of a nerve by fragments of bone and other material, displaced during the passage of a projectile through the tissues, is very common.

The nerves to be frequently damaged in this way are the musculospiral nerve in the arm, and the external popliteal nerve at the neck of the fibula. These nerves suffer quite commonly, being partly or totally torn through at the same time that the bone is smashed. The appearances presented some months later, when the sepsis has so thoroughly cleared up that the nerve repair operation may be safely done, differ very little from those in other cases of complete nerve division.

The cut ends of the nerve may be found widely separated; they are frequently embedded in bone or dense scar tissue. There are the usual "bulbs": the central end terminates in the usual club-shaped swelling, while the distal end of the nerve presents a smaller, harder swelling. The clinical picture is, of course, that of complete loss of both afferent and efferent functions.

2. *Pressure on a Nerve from without:* Constriction of nerves by masses of callus or by organizing tissue following a large concealed hemorrhage, is also a common occurrence among war injuries.

Clinically there may be distinguished three phases in the process. The early signs are those found with bruising or other partial lesion. Next comes a more prolonged stage of irritation pressure. The second stage gradually leads to a third, which is characterized by gradual and progressive loss of function unless the pressure be relieved. The third phase is due to Wallerian degeneration in the nerve fibres, and will show all the signs and symptoms of a complete nerve division in severe cases where the pressure has lasted for a long time. The simple cases of pressure due to the use of crutches are easily recognized and call for no further comment.

3. *Fibrosis Following Intense Suppuration—"Ischemic Paralysis":* There is a type of nerve lesion which is apt to follow upon the healing of wounds where much diffuse suppuration has occurred. This type is perhaps one of the most difficult of all lesions, as regards both diagnosis and treatment. During the acute stage the limb affected gives the surgeon much anxious thought. The urgent questions which arise at this time are whether the limb can be saved, or must the affected part be sacrified to save the patient's life.

Undoubtedly injuries to main blood vessels and important nerves must be recognized in order to come to a decision. The type of nerve injury in the acute stage falls into the background of the picture if it be short of complete division. A complete examination is impossible and undesirable when the patient moans with pain if the limb is moved. The testing of voluntary movements is difficult when pain attends on every movement, and protective reflexes are strongly in evidence.

Electrodiagnosis, unless essential to help the surgeon in a decision for or against early amputation, should not be attempted. Sensory investigations are futile in the presence of severe pain.

Clearly all the cases that are thoroughly investigated will be those in which some recovery has taken place, and all the acute symptoms have subsided. We are left with a clinical picture difficult enough to analyze. There are signs and symptoms which may be due to vascular causes, and some which are undoubtedly due to lesions of nerves. In considering the future of such a patient one must know how much is reparable nerve damage, and how much is due to "traumatic contracture" following vascular injury and repair after suppuration. In a word the diagnosis may be to distinguish what is sometimes called "ischemic paralysis" from nerve injury. The diagnosis is often complicated by the fact that both conditions are present in the same case, and the problem is to find out which has the greater share in the production of the signs and symptoms under consideration.

The appearance of the affected limb will vary according to the severity of the lesion. There is always a deformed attitude, some contracture in one or more groups of muscles. The skin in traumatic contracture is atrophic, and it may be that gangrene of the most peripheral parts has occurred.

The muscles affected are wasted and feel like soft coarse-grained wood. The arteries pulsate feebly, or perhaps no pulse is palpable. There is an irregular sensory loss of glove or stocking distribution in these ischemic cases.

The differential diagnosis is considered under the section devoted to that part of the subject.

Pathologically one has few opportunities to study the changes in the nerve trunks of the chronic cases. One or two nerves examined have shown the usual features of Wallerian degeneration which has probably followed local necrosis at the site of the suppuration, or has resulted during the later stages of the repair fibrosis.

NOTES UPON DIAGNOSIS.—*General Remarks:* The accurate diagnosis of the site and extent of the nerve injury, and the gauging of progress by regeneration are so important that many seemingly needless details must be considered before the desired information is available. A reliable examination technique is essential for accurate diagnosis.

So much has been written and is still appearing, which seems to be conflicting, that some standard method of examining and recording these cases is obviously necessary.

Briefly, the chief mistakes that observers make in examining nerve injuries are, firstly, that they examine limbs, especially, which are so cold and cyanosed as to be unfit for an accurate examination, either electrical or sensory.

Secondly, when testing voluntary movements the observer may be misled by mimic movements. These are performed by healthy muscles not usually associated with certain joint movements. When the usual muscles are paralysed the patient learns to overcome his disability by putting into action a muscle, or group, which takes little part when the principal muscles are healthy. For example, flexion at the elbow is performed by the pronator radii teres when the whole of the biceps group, the extensor group, and the supinator longus (brachioradialis) are paralysed. Slight flexion at the wrist is carried out by the extensor ossis metacarpi pollicis when there is complete median and ulnar paralysis. Extension of the phalanges of the fingers by the dorsal interossei is possible when the long extensor group is paralyzed. There are many examples of these mimic movements which in my experience have explained many a supposed early recovery of motor power a few weeks after nerve suture.

Lastly, although this by no means exhausts the list, there is careless sensory examination. The most common errors arise from the employment of too coarse stimuli in testing superficial sensibility. In nerves such as the musculospiral in the arm, or the external popliteal in the leg, where each nerve has no exclusive area to supply with deep sensibility, a moderately coarse touch is felt quite well through the agency of the deep sensory mechanism, even though the nerve be completely divided. The observer almost unconsciously stimulates much too vigorously in an effort to get a positive response from the patient.

Some sensory loss is always demonstrable in complete lesions of the musculospiral and external popliteal nerves, in spite of statements which appear to the contrary. If sufficiently vigorous stimulation be used the patient gives a positive answer because deep sensation is supplied from the ulnar, median and musculocutaneous nerves under the area of skin supplied by the radial with superficial sensation. In the case of the radial also there is a good deal of overlap which varies with each patient within certain limits. In order to avoid tiresome reasoning in the plea for definite technique, the foregoing examples of likely pitfalls must suffice.

The following method of examination has been practised at a very busy General Hospital, over fifteen thousand examinations in the last four and a half years. There was one break of fourteen months, when the observer was in Egypt on other military service. It is not claimed that this method of examination is the best, or in any detail perfect. The best recommendation is that it is practical, and this for a busy department; and also that it avoids the chief pitfalls that beset the path of neurological diagnosis. That others may wish to profit by our experience must be the excuse for giving full details. The essential preliminaries should include short notes, preferably tabulated to avoid undue verbosity upon the following:

1. The nature of the injury, *i.e.* whether bullet or crush, etc.
2. The posture of the patient at the moment when he was injured.
3. Immediate effects, such as pain, paralysis, etc.
4. After-history, which must include details of surgical treatment following the injury.

The injured part should next be carefully scrutinised and notes made under the following headings:

(*a*) Position of wounds and scars.
(*b*) Attitude of the limb as compared to that of the healthy side.
(*c*) Contractures.
(*d*) Mobility of ankylosis of joints.
(*e*) Muscular atrophy, its distribution in relation to nerve supply or joint control. (It should be remembered that muscular atrophy after complete section of nerve is not apparent for a few weeks.)
(*f*) The appearance of the skin with special reference as to the distribution of trophic changes, such as "branny skin", due to delayed desquamation of epidermis, ulcers or blebs.
(*g*) Hairs—their general arrangement, regular or irregular, "goose skin," etc.
(*h*) Vasomotor—color of the skin, edema, etc.
(*i*) Sudomotor—dryness or hyperidrosis.
(*j*) The nails—color, shape, brittleness, and striations.

It should be recalled that mere immobility in splints will give rise to the appearance of delayed shedding of the epidermis and changes in the nails. This was demonstrated by Head and Sherren and has been repeatedly confirmed by all observers.

The next part of the systematic examination may be headed "Palpation". The observer's hand will gently explore the following:

(*a*) Region of scars to estimate the induration, fibrous nodules, or neuromata in nerves superficially situated.
(*b*) Nerve trunks near the scars. The fingers should gently press upon the nerve peripheral to the site of injury while the patient is asked to describe the nature of any sensation caused. Where any regeneration is taking place, the patient may state that gentle pressure, or light taps, over the nerve cause a sensation of "pins and needles", "tingling", "a cold water sensation", or merely a "bursting feeling" referred peripherally to the skin area, which that nerve usually supplies with sensory fibres. The exact peripheral limit on the nerve at which such paresthesia can be so elicited is important, as was pointed out by Trotter and Davies in 1909, and during the war by Tinel. This percussion paresthesia obtained over regenerating peripheral nerves is now often called "Tinel's sign".
(*c*) The joints should next be gently moved in a passive way to demonstrate stiffness, ankylosis, etc., in order to prepare the way for attempts at active movements by the patient.
(*d*) Voluntary movements of each muscle group by the patient should be watched and it is best to observe the tendons one by one so

that mimicry by surrounding healthy muscles shall not mislead the observer. It is useful to place the limb in a "neutral position", so that the weak muscles are not called upon to raise a heavy hand or foot against the force of gravity; or, conversely, are not allowed to have gravity to greatly assist in a movement.

(*e*) Deep palpation of muscles will give an estimate of their tone, or of possible fibrosis. Pain on pressure or pinching of muscle is elicited in most irritative lesions of a mixed nerve.

(*f*) Direct percussion of muscle bellies may be practised to observe the nature of the response called forth by mechanical stimulation. Sluggish contractions of comparatively large amplitude, slowly rising and gradually subsiding, are found in muscle where electrical examination will give the classical "reaction of degeneration". It should be noticed, however, that such slow contractions of even larger amplitude occur also in certain conditions associated with hypothermia classified by Babinski and Froment as "physiopathie" or "reflex contractures". The muscles of a leg or arm examined after prolonged exposure to cold will also give a sluggish contraction of much smaller amplitude if percussed sharply. The tendon responses are not very important in cases of peripheral nerve injury, but should be examined for additional information if necessary.

Sensory Investigation.—A careful examination of the sensory functions should be carried out next in a quiet room upon an untired patient. The objects of this examination are:

1. To confirm and localise a lesion as either in peripheral nerve, parent trunk or spinal nerve root.

2. To estimate the gravity of the lesion, for examination of the sensory function, carefully carried out, is always more reliable than that of the motor functions for this purpose.

3. To obtain an exact record, charted in all details, to form a starting point from which future progress will be judged. It may be stated here that, after vasomotor function, the earliest regeneration signs in divided nerves will come from the reappearance of sensory functions.

There are a few most important details which must be attended to if the sensory examination is to be a reliable guide to progress. The most neglected precaution is that the part to be examined must be thoroughly warmed to body temperature at least. Another essential, now well recognised amongst neurologists, is some measurable or standard stimulus for all investigation of sensory functions.

We must use standardised stimuli so that observations made at regular intervals of weeks or months will be exactly comparable.

Lastly, a careful system of charting, usually by life-size photographs or by diagrams, is necessary for permanent records. With every precaution adopted there are still difficulties created by the patient's varying abilities to discriminate and describe the qualitative changes from the normal sensibility.

Sensory Functions to Be Investigated in Routine Work. 1. Light Touch: This is the function most easily deranged qualitatively and quantitatively by any nerve injury.

The superficial appendages of the skin, especially hairs, are intimately connected with appreciation of light touch, although the deeper structures join with the hairs normally to form a compound sensation of touch and pressure.

It should be our aim, in testing light touch sensibility never to deform the skin so that the sense of pressure is invoked to complicate the sensations felt by the patient. For all practical purposes it is unnecessary to shave the skin before these examinations if the above-mentioned facts be kept in mind. The shaving of an area of skin where sensory regeneration is advanced may cause so much persistent tingling sensation to be felt by the patient that accurate observation may be impossible for some hours afterwards.

Light touch may be usefully tested by light stroking with a camel's hair brush. Most of the hairs should be removed so that the tests will be carried out with a small wisp of about a dozen hairs. If the brush be used carefully so that the hairs sweep the surface at an acute angle, and with little or no bending during contact, reliable results are obtained.

The use of calibrated hairs after the method of von Frey, is more accurate, but the method takes too long for any but specially selected research cases. Cotton wool wisps are unsatisfactory. The area of complete anesthesia to light touch should be marked on the skin and charted later.

The area of qualitative change will be marked out next. This latter area usually takes the form of hypoesthesia and is wider than the area of complete tactile anesthesia.

2. Sensation to Pin-Prick: Pin-prick is often used as the test for pain sensations. The stimulus is really a compound one and gives rise to a sensation of sharpness and another of pressure.

In the complete nerve lesions the sensation of sharpness will be found to be abolished over a wide area as a rule, usually outside the area of anesthesia to light touch with a brush.

A sensation of blunt pressure, and it may be of painful pressure, is felt by the patient usually a little distance before the limit of anesthesia to light touch is reached. For the purpose of testing pin-prick sensation the use of an instrument such as the spring algesiometer devised by Head and Holmes, or other algesiometer, is necessary.

Head's algesiometer consists of a needle mounted on a spring, the pressure of which can be adjusted. A standard stimulus is thus obtained and the figure at which the spring is set is charted for comparison with future readings.

3. Deep Sensibility: Bones and joints are endowed with sensation to vibration, movement, etc.

The subcutaneous tissues, muscles, etc., are sensible to pressure and pain, even in the absence of sensation to light touch and pain in the more superficial structures.

4. Pressure Sensations: Pressure sensation may be roughly tested by pressing deeply into the skin

with the blunt end of a pencil. This may be all that is required to complete the evidence pointing to a total loss of sensory functions in a peripheral nerve.

More exact methods to obtain the threshold value of the stimulus required to excite deep sensation are necessary to gauge progress during regeneration. Some form of algometer capable of exerting measurable grades of pressure is desirable. The instrument should have a contact point which is equipped with a blunted guard about a millimeter in diameter. Graded pressure is then obtained by the addition of small metal weights.

The algometer of Head and Holmes is a useful instrument although its weight range is small for work on the leg and foot. The algometer is used for noting and measuring the threshold stimulus, and it may also be used for allowing the patient to discriminate between varying pressures on the same unit area.

5. Localization: The localization by the patient of the spot stimulated is conveniently observed during the examination of sensations to light touch, pin-prick, etc.

The patient indicates on a life-size diagram, or photograph, the exact spot where he feels the touch, pin-prick, etc.

The foregoing tests are all that are essential from a diagnosis point of view when peripheral nerves only are damaged. It is unwise to tire the patient, or the investigator, by making too long an examination.

Perception fatigue of the patient, or too much routine for the observer, lead to the compilation of careless records. Where there is reason to believe that the injury or the disease may affect spinal nerve roots, or the cord itself, some further sensory tests are made.

6. Thermal Sensibility: Strictly comparable records of a patient's sensations to heat and cold are difficult to obtain.

The varying temperature of the patient's skin makes a sound technique a laborious business. The skin cannot be adapted to heat or cold without materially altering the sensations that the patient will experience when the thermal tests are applied. Certainly it is wise to examine all these patients in a warm room, and in winter there is little objection to a preliminary warming of an arm or leg to body temperature in a hot-air chamber, or in warm water.

For the actual tests the writer has used small nickel-silver test-tubes which taper to a blunt end measuring exactly one square millimeter. The tubes are fitted with corks through which project centigrade thermometers. Goldscheider's pointed solid metal cylinders, or a moderately thick copper wire, will be found useful for minute observations upon the distribution of the hot and cold spots on an area of skin. In complete injuries of peripheral nerves the sensation of heat is abolished and is slow to return.

Cold sensations are obtained by the use of other stimuli than thermal excitation. Mere pressure on a regenerating nerve will often call forth a remark from the patient that he feels a sensation like very cold water in the area anesthetic to all but deep sensation.

Our work during the last four years has led to the conclusion that pain sensations and sensations evoked by extremes in temperature are intimately bound together. Trotter and Davies suggested that very hot or very cold stimuli give rise to compound sensations of a thermal and painful nature. Our independent opinion was arrived at before the work of Trotter and Davies was known to us, and is largely in agreement with their observations.

For purely thermal stimuli it is necessary to use temperatures not very remote from the ordinary skin temperatures. In lesions of peripheral nerves the area of the thermanesthesia corresponds more or less irregularly to the area of loss to pin-prick, and then outside this area there is a wide area of thermohypoesthesia, where active heat and cold spots seem to be spread out more sparsely than on the healthy side. The value of thermal stimuli is well known in the diagnosis of such injuries to the lateral column of the spinal cord as will give a Brown-Séquard syndrome.

The accompanying diagram (Fig. 1) shows the distribution of the sensory disturbance in such a case.

There will be on the same side as the damage atrophic paralysis at the site of injury, while the muscles below will be weak and spastic, with increased tendon jerks. The sensory changes in this limb are not striking, but in the apparently sound limb there is profound loss to heat, to cold, and to painful stimuli.

Such a patient once told the writer that in getting into a hot bath he always tried the temperature with the weak leg as the other was unreliable, and had at first led him to enter a bath much too hot for him. This man had a rifle bullet in his spinal canal, and did not know that he had been wounded. Apparently he was immediately buried by the fall of a dugout, and when he came under my observation he was being treated for "shell shock."

7. Weber's Test: The recognition of two blunted points of a compass, applied simultaneously to the skin in the long axis of a limb, is a function associated largely with deep skin sensations of pressure. The subsequent path follows that of deep sensation from the joints and musles into the posterior columns of the cord.

8. Vibration Sense in Bones, etc.: The bones are normally sensitive to the vibrations of a large tuning fork except when deep sensation is abolished, or when the posterior columns of the cord or root ganglion cells are injured or diseased. This latter statement is in contradiction to the current view that the lateral columns conduct vibration sense.

Difficulty in estimating pallanesthesia will result from "overflow vibrations" to neighboring joints. The handle end of the tuning fork should be placed on the bone at right angles to its long axis for the best results.

9. Discriminating Sensibility: Discriminating sensibility is relatively unimportant for the diagnosis of peripheral nerve lesions. The size and shape of common every day objects should be distinguished by the patient's unaided skin sensations. Such objects as matches, coins, a pencil, etc., are placed in the man's hand and he rolls each in turn

between his fingers if the lesion permit of this.

The discrimination of textures such as silk, cotton, wool, india rubber, etc., is also tested. This further examination is more important for cerebral sensory lesions than for peripheral nerves. In lesions of peripheral nerves there is no doubt that discriminating sensibility is the last function to be restored, largely because it requires perfect sensory impressions from the peripheral skin.

The Electrical Examination.—The skin must be thoroughly warm and moist so that the resistance to the electrical current will be as low as possible. For the examination we require a rapidly interrupted current of short duration which will appeal to the nerve and nerve-muscle, and a slowly interrupted constant current, a stimulus of relatively long duration, which will stimulate the muscle directly even though the nerve be degenerated.

It matters little how these currents are obtained and measured. A set of condensers with capacities

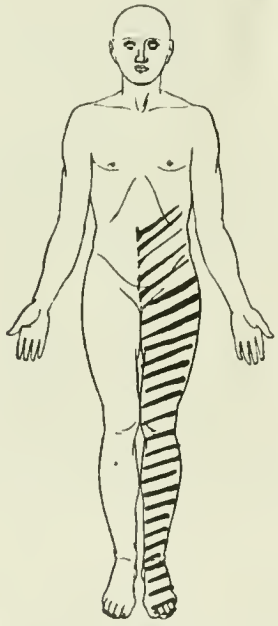

FIG. 1.—Diagram showing the distribution of sensory disturbances. Right leg: Spastic reflexes and Babinski's sign present; loss of joint and muscle sense. Left leg: Normal motor functions; thermanesthesia, analgesia.

varying from .025 microfarad to about 4 microfarads may be used from a constant current supply of steady voltage. The small condensers supply the current of short duration, while the large condensers take a longer time to discharge and supply the long duration stimulus. The Lewis Jones condenser set is used by many observers and proves quite a convenient method of testing in electrodiagnosis.

The advantages claimed for the condenser method are that it is painless, and that an exactly measurable electrical stimulus is used. In practice we have found the method to be disappointing. Exactly measurable electrical stimuli, applied through such variable resistance as is set up by the human skin, lose much of their value.

The electrodiagnostic methods which rely on averages or upon the character of the muscular contractions prove to be more valuable than those which aim at exact readings.

The following apparatus will be found to fulfill all requrements for nerve-muscle testing:

1. A short medical induction coil with a good interrupter to give stimuli at the rate of about one hundred per second. The current from the secondary is employed.

2. Some means for varying the strength of the current. The best arrangement is the movable secondary on a "sledge," after the suggestion of Du Bois Raymond.

3. Electrodes, one large and one small. The smaller is mounted on a wooden handle to which is fitted a "make and break" key. A clockwork metronome with mercury dip may replace the key if desired.

4. A constant current circuit to which is fitted a shunt resistance rheostat so that the amount of current in the patient's circuit may be varied. A milliampèremeter should be attached to this.

5. A "pole reverser" switch, which changes the direction of the current flow in the external circuit, completes the apparatus.

Where there is a constant current of low voltage available it is a great convenience to work both the galvanic and the faradic apparatus from this, and have them mounted on the same switchboard. Most instrument makers supply this combined switchboard, which answers all purposes.

Method of Testing.—Faradic Test: The connecting wires are attached to the terminals of the secondary coil and to the electrodes. The large electrode covered with lint is dipped in warm tap water, and placed at the root of the affected limb, or strapped by a rubber strap to a part of the patient's surface where bones are well covered by the soft parts.

The small, or "active electrode," is placed upon the "motor points" of each of the muscles in turn, and lastly upon the nerve trunk. The tendons or muscles are closely watched for evidence of contraction, and the character of each contraction is carefully noted.

If all the muscles supplied by a nerve react to faradïsm a week after the injury one may definitely exclude a total lesion of that nerve.

Hysterical or "pithiatic" cases, "functional" cases as a whole, cases of "physiopathic" or "reflex" contracture, cases of malingering, and also organic damage to the upper motor neuron in the brain or cord, are all associated with a positive reaction to faradic stimulation. In total lesions of peripheral nerves, where recovery is advanced, voluntary motor power usually, though not invariably, returns before a positive response to faradism can be obtained.

Character of Muscular Contractions: A brisk twitch with moderate amplitude occurs in the healthy state.

One observes slow sluggish contractions of small amplitude in cold limbs, disuse atrophy following prolonged splinting, and in some recovering total lesions of nerves.

There is increased excitability with large amplitude and usually a quick response in cases of "reflex" contracture, and in some functional cases.

There is no muscular response whatever when a total lesion of the nerve supply is present.

Galvanic Test: The "make" and "break" key

work by hand provides what we may call the stimulus of infinite duration, at least so far as nerve excitability is concerned.

The electrodes are placed as before, and, if the combined switchboard is being used, all that will be necessary is to lock the switch leading to the galvanic circuit.

The small electrode is first made the cathode, and the amount of current which will just produce a contraction on closing the circuit is used. The current is then broken and the pole-reverser swung over so that the active electrode now becomes the anode. The observations are repeated and the character of the muscle contractions noted. We may recall that under normal conditions in a perfectly warm limb a brisk contraction will occur under the cathode at each closure of the circuit when a weak current is used. A smaller contraction, though equally brisk, will occur when the anode is used over the same muscle.

When the muscle is deprived of its nerve supply completely, and time has been allowed for Wallerian degeneration to occur in all the nerve fibres, the character of the muscle response changes. The changes are, briefly, an increased amplitude of contraction with a slowly rising, slowly subsiding response. The contraction starts from the neighborhood of the electrode, and spreads in both directions along the muscle in a curious sluggish, vermicular manner. Such a contraction obtained in a perfectly warm limb is quite characteristic of denervation of the muscle. The variable polar changes with increased excitability to the anode, are less important though the whole described picture forms the classical "reaction of degeneration."

A full discussion of all the changes which occur in the excitability and conductivity of nerve is out of place here. Much important work has been published lately by Lapicque, Keith, Lucas, Adrian, and others upon nerve conduction, and in their papers workers upon this subject will find much guidance.

The purpose of this paper will be better served by emphasis on main types rather than by a lengthy account of injuries to individual nerves. The idea throughout is to give a clear picture of diagnosis which will indicate a definite line of treatment at the earliest possible moment.

FIG. 2.—A case of complete lesion of the ulnar nerve, the picture shows the contracture which takes place occasionally in the muscles supplied by this nerve.

COMPLETE LOSS OF FUNCTION IN A NERVE TRUNK.—*Signs and Symptoms.*—Attitude: There is complete flaccid paralysis in the affected muscles, and, after an interval, atrophy in these, with possible contracture due to the unopposed action of their opponents. In neglected cases there may be shortening due to fibrosis in the paralyzed group so that the contracture alters.

Joints: Arthritic changes occur, and with contracture there is alteration in joint axes, and in supporting ligaments. There is never bony ankylosis.

FIG. 3.—Showing contracture in the muscles supplied by the median nerve, which is completely divided in this case.

Muscles: The paralysis falls upon a certain group or groups. The atrophy is related to nerve supply and not to joint control, as in arthritic muscular atrophy. The muscles are flaccid and show increased mechanical excitability when percussed directly.

The response to tapping is slow and vermicular rather than the sharp contraction which occurs in health.

Tendon reflexes are abolished.

Deep palpation of muscle is not uncomfortable.

Skin: The skin is dry and scaly, very quickly a "branny" appearance is noticed.

Vasomotor Blush: *The color of the skin is usually altered to a reddish blush* over an area corresponding closely to the skin distribution of the affected nerve. In cold weather this area is swollen, cyanosed, and liable to chilblains.

Hairs: The hairs are irregular, and suggest the appearance of a cornfield after a heavy rainstorm.

FIG. 4.—Showing trophic disturbance in a case of ulnar and median lesion. The delayed shedding of the epidermis is well seen.

"Goose-skin" reflexes are absent over the skin area supplied by the nerve affected.

Nails: The nails quickly alter their color and elasticity. They become brittle, dry, curved, and ridged. The epithelium is heaped up under the

nails, so that the ends of the fingers suggest a horse's hoof in marked cases.

Palpation of Nerve: The observer's fingers may be able to detect a slight swelling at the site of the injury on the nerve, if it be superficially placed. If the nodule be gently compressed the patient may state that he feels an unpleasant shock or pain running down the limb toward the known skin supply of the nerve. Palpation below the site of injury, and even firm percussion, causes no sensation other than the local feeling of a slight tap to the skin. There is no Tinel's sign.

Sensory: There is complete loss to light touch over the skin area supplied, and outside this there is a large zone of hypoesthesia. Certain nerves, such as the musculospiral in the arm and the external popliteal division of the sciatic, vary much more in these areas of sensory loss than nerves which have an area to supply with all forms of sensation, including deep sensibility. This is readily explained by the variable "overlap" possible where one or more nerves send fibers into a given area. Pin-prick sensation is lost over an area almost as large as the loss to light touch, and when it is appreciated it is not the normal sensation of sharpness. The sensation of sharpness is not elicited until the algesiometer is working well outside the area of total loss to light touch.

Thermanesthesia closely corresponds in its distribution to that of loss of the sensation of sharpness, unless very cold stimuli be used. Very low temperatures do not provide purely thermal tests, and should not be used for routine examination of thermesthesia.

Deep Sensibility: The area of loss of deep sensation, *i. e.* joint sense, muscle sense, deep pressure, pressure pain, and vibration sense, varies with each nerve. In a total lesion of the median above the wrist there is loss of deep sensation in the two terminal phalanges of the index and middle fingers. The terminal phalanx of the thumb may be also involved. A total ulnar nerve lesion above the wrist produces deep sensory loss only in the terminal phalanx of the little finger, though the second phalanx and its joint are also frequently involved. A total lesion of the median and ulnar nerves together gives loss of deep sensibility over the two terminal phalanges of all the fingers, the whole of the little finger, and a variable area of the ulnar margin of the hand on its dorsal and ventral surfaces. Sometimes the thumb-nail pulp and about an inch of the palmar surface of the thumb are insensitive to all stimulation.

A total lesion of the internal popliteal division of the sciatic produces complete deep sensory loss over the smallest toe, and the terminal phalanx of the fourth toe. Quite frequently the deep loss extends to the terminal phalanges of all the three outer toes and the adjacent plantar surface of the foot on its outer side. There is no total loss of deep sensation when the external popliteal nerve is divided alone. If the whole sciatic nerve be divided the deep sensory loss is very extensive.

The whole of the sole of the foot, except a half-moon-shaped area on its inner side, is insensitive to all stimulation. There is complete deep loss over the toes, metatarsals, and external malleolus. The tarsal bones are usually insensitive to vibrations, though the ankle joint retains some sensibility. There is a zone between the area of total loss and that of normal sensation where the subject feels deep sensations in a modified and reduced manner.

The above facts have been verified by analysis of many records of total lesions, and prove most reliable in the diagnosis of such lesions.

Electrodiagnosis: Electrical examination a few weeks after the injury usually gives a complete and classical R. D. If the responses are brisk to the galvanic current, and all the other functions are abolished, the case is probably one of complete division, nevertheless. A slight and persistent briskness in the galvanic response *usually* means that a few healthy, though possibly unimportant, nerve fibers remain peripheral to the injury. Microscopic examination of nerve tissue removed at the operation has proved that this test is superior to the naked eye inspection of the nerve to decide the presence of a few healthy nerve fibers in an injured nerve.

Indications for Treatment.—A clinical picture of total lesion, which remains without a sign of regeneration for twelve weeks after the injury, should be surgically repaired at once, if possible. Surgical considerations will lead to delay where bone sepsis and prolonged suppuration in the soft parts have been present.

The surgical repair of nerves and the technique to be employed by the surgeon have been fully dealt with by others, and nothing will be added here except to note that the gloomy outlook upon autogenous nerve grafting operations will have to be abandoned.

Cases where a six-inch gap in the median nerve of the arm has been bridged by a length of internal cutaneous, have shown a slow but sure return of function. Muscles formerly paralyzed are now working quite well, and sensory restoration has been even more complete. The end results are not yet obtained, progress still continues, although the operations were performed over two years ago.

After-treatment.—If a well-equipped massage and electrotherapeutic department is available, with a carefully trained staff, there is nothing more important than an early return to treatment in this department after nerve suture.

The surgeon will direct what splints are to be worn, and will also state in general terms what movements are to be attempted in the early days after the operation.

Where possible the splints should be removed daily for gentle massage and passive movements of the peripheral joints to prevent stiffness. The whole object of both massage and electrical treatment is to keep up the nutrition of all tissues artificially until a healthy blood supply and normal movements are restored.

The most perfect recovery of nerve will be a poor practical result to a man who works with his hands if all the joints are stiff and his fingers permanently deformed by contracture. The electrical treatment for a fortnight after operation should be confined to applications of medical diathermy locally to the affected limb. The constant current is also useful in the early days after nerve repair. Both these agents merely improve the local circulation. As soon as possible the early treatment should be accompanied

or replaced by the use of interrupted galvanism, which is carefully applied to each paralyzed muscle separately. In this way all the powerless muscles are exercised artificially for a short time each day.

The use of bath electrodes in which a whole limb is immersed is to be deprecated; it leads to careless treatment, in which the healthy muscles are excited, rather than those that most require attention. The most attractive rhythmical interrupters do not overcome the disadvantages in the use of the bath electrode for this type of case.

As soon as a flicker of voluntary power occurs in a group of muscles electrical treatment should be stopped and active exercises to reeducate the muscle movements instituted.

Much persistent incoordination after nerve suture is due to want of careful reeducation of muscles. During the paralysis all sensory and motor impulses are stopped. The patient learns to do without his paralyzed group by educating other muscles to take on their work to some extent. Careful reeducation of recovering muscular power forms a very essential part of the after-treatment of all nerve lesions.

Reeducation is best carried out in a gymnasium, and various exercises will be planned in the form of a game to prevent the treatment from becoming a dull routine drill. In the later stages, scientifically arranged exercises in a curative workshop are the best of all. The patients are most keen and interested when doing productive work in a workshop.

INCOMPLETE LESIONS.—*Signs and Symptoms.*—(*a*) The early signs and symptoms in the first ten to fourteen days after the injury may be those of the complete lesion, except that reaction of degeneration cannot be relied upon so early. In partial lesion, however, there is more pain and a deep "bruised feeling," which the patient describes as felt under the skin distribution of the injured nerve. There is never the complete loss of deep sensibility that occurs in the complete lesion.

(*b*) After the second week, when, presumably, all local bruising and edema at the site of injury have cleared up, the signs and symptoms become definite. The vasomotor and trophic disorders are mild, or even absent.

The paralysis may be limited to a few muscles or a whole group supplied by a nerve; or there may be merely a transient paresis of all the muscles. The electrical responses may show a complete abolition of faradic excitability in one or more muscles of the group without the sluggish galvanic responses associated with R. D. When one or two muscles only remain permanently paralyzed it is exceptional to obtain the classical R. D. contraction with polar reversal. The presence of a few conducting nerve fibrils in an injured nerve is quite enough to give modified electrical responses which are short of R. D.

The sensory changes are characterized by the retention of deep sensibility, and more or less severe interference with the other sensory functions. There is usually a wide area of hypoesthesia to light touch, and, it may be, complete tactile anesthesia. The pin-prick sensation is much diminished, as a rule, though there may be irregular areas where unusual pain and sharpness are felt by the patient.

Indications for Treatment.—All "partial lesions" should be most carefully examined and charted at the first examination so that their progress may be regularly noted.

Regeneration signs appear in a few weeks, and

FIG. 5.—A case of irritation syndrome in the median nerve. The hatched area in the palm was the seat of hyperalgesia to all forms of stimulation.

if these progress steadily the patient may be expected to recover by the use of massage, electrical and reeducation treatments.

In some cases the signs and symptoms remain stationary after the first few weeks. There has evidently been a complete lesion in a few nerve fibers only, and the associated muscles and sensory apparatus fail to improve. Where progress is arrested in this way for two months, or where retrogression has occurred, surgical intervention is then indicated.

The healthy motor fibers will be picked out, when the nerve is exposed at the operation, by the application of a small sterile electrode and the use of a weak faradic current.

The after-treatment is the same as for the complete lesion.

THE SYNDROME OF IRRITATION.—It should be made clear at once that the cases which show irri-

FIG. 6.—The same as illustrated in Fig. 5, showing the dorsal distribution.

tative phenomena are all cases of partial lesion. The main causal factor in the production of the pain and other symptoms which constitute this syndrome is fibrosis in the nerve trunk.

We never see severe irritative phenomena earlier than the tenth to the fourteenth day after the injury. The symptoms and signs will vary according to the amount of destruction caused at the site of the injury. Where there is little destruction, as in cases of simple hemorrhage into the nerve and later fibrosis, we find little or no motor paralysis, though the patient may complain of the most intense pain. To these terrible cases Weir Mitchell gave the name "causalgia," to indicate the "burning pain" which most of these patients describe. The reader cannot do better than consult Weir Mitchell's monograph for the now classical description of these cases.

The clinical details which he described as occurring in the wounded of the Civil War, in 1863, have been repeated on a larger scale during the World War of 1914-18. Our experience and investigations all go to prove that the whole picture results from an irritation set up in the central end of an injured portion of the nerve. Painful impulses travel to the central nervous system and efferent impulses provide the rest of the picture in vasomotor, sudomotor, obscure "trophic," and other details.

There is never complete solution of nerve continuity in these cases. There have been many other theories put forward of late years to explain the symptoms of causalgia, such as associated vascular lesions, injury of sympathetic fibers, and so on. None of these theories has stood the test of experience. Weir Mitchell comes very near the truth of the whole matter when he states: "Further study led us to suspect that the irritation of a nerve at the point of the wound might give rise to changes in the circulation and nutrition of parts in its distribution, and that these alterations might be themselves of a pain-producing nature."

Indeed, all the signs and symptoms of "causalgia," and the less painful though closely allied forms of irritative lesion, can be explained by modified afferent impulses and efferent reaction to these.

The clinical picture of true causalgia is quite easy to recognize. The patient complains bitterly of pain. It is usually a median or internal popliteal nerve that is affected. The palm or the sole continually burns and feels as though it must burst with pain. Warmth and dryness cause the patient much misery, whereas cold, and certainly moisture, relieve the pain a little. For this reason the patient will carry a moist handkerchief continually in the affected hand, and may even carry one on the sound side—another suggestive fact to prove the reflex influence in these cases. Sleep is difficult to obtain, and patients may ask for amputation or threaten suicide.

There are motor paresis and slight contracture. Sensory examination is almost impossible because pain makes an analysis of sensory impressions out of the question. The skin in early cases shows a pink flush, and the fingers become conical. There may be small, scattered, pinhead vesicles under the skin. Later the skin becomes glossy and atrophic. Large blebs, such as result from superficial burns, appear at intervals. Patients have repeatedly watched these blisters rise in an hour or two; the writer has confirmed this. There is no question of trauma in the production of these trophic blisters; they occur upon a hand carefully wrapped in a flannel glove all day; a hand too painful to use, or even to swing at the side when walking.

Mentally these patients become wrecks. One of the cases (see Figure 8) was diagnosed by an experienced colleague as "congenitally imbecile." The patient was subsequently cured, and so changed in appearance that the physician thought he was another patient.

Fig. 7.—A case of severe "causalgia" in a female patient. The lesion was due to gouty deposit in the nerve. The trophic blisters were actually observed as they were forming. They are purely trophic, not traumatic.

Fig. 8.—The appearance of the palm in a case of severe "causalgia," in a man thought to be mentally defective. The trophic changes and contracture are well shown.

Less Pronounced Types than Causalgia.—There are varying grades of severity, from causalgia to cases where pain is mentioned by the patient only upon questioning him closely. These cases all have

varying degrees of motor and sensory loss with contracture. The picture will entirely depend upon the amount of destruction caused at the site of the injury.

The general signs are those of a partial lesion with an unusual amount of semicontracture in the affected muscles. There is pain when the muscles are gently pinched by the observer, and particularly when one presses on a nerve trunk. This elicited pain may not be of a burning character, but like "a sharp knife stab" or a "deep, painful bruise."

The discomfort present during the later stages of regeneration must be carefully distinguished from the pain of irritation syndrome.

During the knitting together of young scar tissue, compression symptoms are caused; these may include pain severe enough to be classed with the syndrome of irritation.

The increasing density of the fibrosis often results in gradual motor paralysis and increased sensory loss, when the pain may cease.

Prognosis.—We have many times found that severe cases of minor causalgia clear up in a few weeks, slowly, without active intervention at the site of injury.

When the pain and other features do not show any sign of amelioration in eight weeks we advise surgical intervention. Surgical treatment may be indicated much earlier in the most severe cases, where the relief of pain is the most urgent necessity.

When there are signs of increasing compression on the nerve, shown by decreasing muscular power and loss of sensory functions, then operation is at once advisable.

Indications for Treatment.—The safest and best surgical procedure for all severe causalgia is excision of the affected portion of the nerve, followed by end-to-end suture, or nerve graft if the gap be a large one. This may seem too drastic when the local condition of the nerve, as seen at operation, looks so good. It is not too drastic when one knows that failure to cure the condition will lead to a uselessly painful, contractured extremity, if not to death of the patient by suicide. For the less severe cases, and especially where there is very evident local fibrosis, a partial operation is done and the nerve replaced in a new muscle bed, if possible, to prevent subsequent fibrosis. Other procedures, such as injection of alcohol, have been found to be comparatively useless, as well as uncontrollable and clumsy in their action. Too much is hoped from chemistry when alcohol is injected, and not enough is attempted by really delicate workmanship. Injections aim at the treatment of the symptoms, when we ought to search for and treat the cause of the symptoms in order to cure the patient.

Signs and Symptoms of Regeneration.—It must be understood that the signs of a recovering lesion and the date they appear vary very much with the nerve affected. There are general indications which are, however, common to all recovering lesions, and with these we now deal. Regeneration of nerve fibers proper takes place from the cut end attached to the central nervous system.

We have never found any cases of phenomenally early recovery after complete division, nor any proof that regeneration occurs in the peripheral cut end.

Preparatory changes do occur in the cut end, but the actual nerve fibers must grow slowly from the proximal end into the peripheral channels prepared to receive them.

Regeneration is quicker in summer, slower in winter, and may occur in small spurts, although, on the whole, it is a regular growth.

Early Signs.—The first signs noticed after nerve suture are of a vasomotor nature. The skin becomes a more healthy color, so that we can no longer guess the area of anesthesia from the color of the skin. The vasomotor recovery occurs too early for actual downgrowth to have occurred; it will be noticed within a month of nerve suture. In long nerves like the sciatic it may be eight to twelve weeks before the color of the skin changes.

The Skin.—Changes soon occur in the skin after the vasomotor recovery. There is a more normal desquamation, and the nails become less dry and brittle. Trophic burns or sores quickly heal.

Nerve Trunk Sensibility.—The next change is one of altered sensibility elicited when the nerve is gently pressed upon, or tapped, just below the suture line. On mechanical stimulation the patient describes a "tingle" or "pins and needles" sensation, referred to the skin distribution of the nerve. This

Fig. 9.—A case of complete lesion of the median and ulnar nerves. The picture was taken several weeks after repair of the nerves, and it will be noticed that the skin is already assuming a normal appearance.

sign, fully described by Tinel, appears very early after nerve repair; usually, in four to eight weeks it is unmistakable. If regeneration is proceeding normally the sign is obtainable at lower levels on the nerve at every monthly examination. When recovery is arrested by scar formation the level at which the "pins and needles" sensation can be elicited remains the same for several weeks. All cases in which the sign remains stationary should be carefully examined in case the arrest of progress is due to some serious mishap in either general health, or local conditions at the site of suture.

A Tinel's sign must be carefully distinguished from the pain caused by pressing a nerve where an irritation syndrome is present. In the former the sensations are referred to the periphery, while in the latter the local pain is the feature emphasized, while the referred sensation is hardly noticed.

Deep Sensation.—The next functions to reappear are the deep sensations. Joint sense and sensibility to deep pressure appear first. The sensation is much changed from the normal. It is indefinite, and of a diffuse tingling quality. There is an exaggerated feeling of discomfort when deep pressure is made over an area formerly the seat of deep anesthesia. Muscle sense appears later, and is below normal for many months, as is the exact localiza-

tion of pressure. The exact date at which one may expect the restoration of deep sensation varies greatly. In the ulnar nerve the earliest recovery was thirty days after suture at the wrist, and the most delayed reappearance was two hundred and twenty-four days, after suture in the upper arm. These figures are obtained by analysis of over 400 cases of ulnar nerve injury. After the return of the deep sensations it is but a short step to the recovery of the skin sensations to coarse stimulation.

Pin prick is felt first, though as a blunt sensation, and then the coarser grades of "touch pressure."

It is interesting to note that touch which is just short of deforming the skin will be appreciated as a curious "pins and needles" feeling first in the highest part of the former area of anesthesia. As a rule, the part nearest the central nervous system regains sensation before peripheral parts. The regeneration soon becomes patchy, and light touch is appreciated as a "numb sensation." The patients state that the quality of light touch is very little altered from the normal side, except that it is indistinct, irregularly felt, and "numb." The tingling "pins and needles" feeling persists for months after the return of voluntary motor power. The average time from the date of repair to the reappearance of hypoesthesia to light touch in the median and ulnar skin areas was seven months.

Sudomotor.—Sweating is restored with sensibility to coarse stimulation, such as pin prick and coarser grades of touch.

Motor.—The return of voluntary power will largely depend upon local conditions and the nerve affected. In all the cases that we have watched the highest muscles of a group regain their power first after complete lesions, and then successively the lower muscles. After suture, including favorable and unfavorable cases, the averages are:

(*a*) Ulnar suture in the upper arm is followed by voluntary power in the flexor carpi ulnaris in six months, and voluntary contraction of the intrinsic muscles of the hand in fifteen months.

(*b*) Median suture in the upper arm is followed by power in the median flexors of the wrist in five months, and in the abductor and opponens pollicis in eighteen months.

The averages are very much the same in the case of the sciatic nerve and its branches.

There is no precision in the time intervals between repair and recovery. The whole process is, as one might expect, largely an individual matter, although nerves repaired soon after injury recover more quickly than those where delay has been unavoidable.

That a nerve has not been repaired reasonably soon after the injury is usually due to some unfavorable local condition which of itself will probably influence the speed of the regeneration process.

Pilomotor.—The pilomotor functions are still imperfect when there is good movement in the deeper muscles. The pilomotor apparatus does not seem to recover until discrimination of the various skin sensations is well performed by the patient.

Discriminating Sensibility.—Perfect discrimination between the various forms of skin stimuli is the last function to recover. In our cases complete total recovery of this function is comparatively rare yet. Active restoration of sensation still proceeds in cases where the nerves were repaired in the winter of 1914-15.

Thermal Sensibility.—Thermal sensations are unreliable as evidence of the progress of regeneration; they are therefore considered last. In the early stages of regeneration it is quite common to find that the patient experiences some "icy cold" sensations to other stimuli than thermal or painful ones. Heat as a pure thermal sensation is abolished in the complete lesion, and reappears long after cold can be appreciated by the restored sensory apparatus.

Conditions Which Simulate Peripheral Nerve Injury.—1. *Traumatic Contracture* (sometimes called "Volkmann's Ischemic Paralysis")—This condition in its early stages, and much more frequently in its later phases, may be confused with a purely nervous lesion.

Fig. 10.—A case of "traumatic contracture" following upon vascular lesions and intense suppuration. The superficial gangrene of the skin and contracture of the fingers are obvious.

A consideration of the nature of the injury helps greatly in the making of a diagnosis.

The patient has often sustained damage to the main blood vessels at the root of a limb. Hemorrhage has led to the ligature of large vessels in order to save the patient's life. After a transient pallor and numbness of the whole peripheral part of the limb there succeeds a period of edema and intense pain. The bloated appearance of the part, its powerlessness, and pain are the main features at this stage.

These symptoms are also found in many extensive septic inflammatory conditions, especially in those which spread deeply amongst the tissues after battle injuries.

The later stages of the "ischemic" cases are characterized by a shrunken contractured state of a hand or foot with atrophic skin, and perhaps patchy superficial gangrene of the fingers and toes.

The trophic changes are a most marked feature. The muscles feel hard, wooden, and atrophic, and have lost their properties as muscle. The mechan-

ical and electrical excitability is lost in the most pronounced cases, and seriously reduced in all.

The sensory loss is of a glove or stocking type, quite unlike that due to nerve lesions.

There is much pain often of a referred nature. The nerve trunks may be painful to pressure higher up the limb. There is an exaggeration of deep pressure pain. Less characteristic forms are sometimes difficult to distinguish from the true irritation syndrome of nerve. The vascular lesions will give valuable help in diagnosis, as well as the distribution of the sensory loss.

2. *Organic Paralyses of the Upper Motor Neuron Type.*—This type of case, especially where it is due to some spinal lesion such as hemorrhage around the cord, or a Brown-Séquard syndrome, may at times simulate peripheral nerve injury. The history and nature of the injury, the state of the reflexes, the distribution of sensory change, and the character of the electrical responses, will serve to make a correct diagnosis an easy matter.

3. *Poliomyelitis, Acute Infective Polyneuritis, etc.*—The above diseases are distinguished by the history of the lesion and by the electrical reactions. The extent of the sensory loss will serve to distinguish the lesion as in the anterior horn of the cord, nerve roots, nerve trunks, or individual peripheral nerves.

4. *Pithiatic (Hysterical) Paralysis or Contracture.*—These cases are surprisingly frequent after trivial injuries. Many patients are men who do not show the exaggerated emotional state so commonly found in civil practice. The deformity is usually a striking one, and is usually an exaggerated picture of some paralytic deformity.

Unusual and often paradoxical attitudes are a feature of many cases. A man may be unable to use his leg to walk and yet the muscles are thrown into vigorous action when tested with the patient lying on his back (astasia abasia). Above all, the contractures and paralyses vary from day to day and may alter even during the examination. The reflexes are never materially altered in these cases, and the vasomotor disturbance never exceeds a slight coldness and cyanosis from disuse.

There are no trophic disturbances unless the patient deliberately manufactures these by burning

Fig. 11.—A typical case of "physiopathic contracture" affecting the hand. The case was slowly cured by reeducation and thermal baths.

his fingers and so forth. The electrical reactions show little but quantitative change from the normal state. Finally, the symptoms clear up in a few minutes, or hours, under treatment by persuasion and manipulation.

5. *Physiopathic Contracture* (Reflex Paralysis of Babinski and Froment, "Acromyotonus" of Sicard).—This condition is described apart from cases of undoubted hysteria because of some characteristic features which it possesses. It is much

Fig. 12.—Same case as shown in Fig. 11, dorsal aspect.

debated at present whether it is a clinical entity allied to the reflex paresis and atrophy described years ago by Charcot, or whether it is purely pithiatic in origin. Babinski and Froment, with others, hold that these physiopathic cases are something more than hysteria, while Roussy and L'Hermitte, as well as many observers in this country state that the whole of the symptoms can be explained on the grounds of hysteria and disuse.

The chief features of these reflex contractures are as follows:

(*a*) The initial injury is trivial, a skin wound or crush without fracture.

(*b*) The affected part is cold, cyanosed, and may be markedly edematous.

(*c*) The paralysis is not as a rule absolute. There is a spastic contracture of one group of muscles with weakness and atrophy of their antagonists. In the foot the commonest type is the club foot associated with atrophy of the peronei. There is a spastic tibialis anticus as well as a sustained contracture of the plantar flexor group.

The combination is thus quite unlike organic injury of the external popliteal nerve, where all of the anterior group are paralyzed together.

In the upper extremity an exaggerated form of drop wrist with contracture of the flexor group is found. The thumb and fingers are adducted, the

Fig. 13.—A case of "drop wrist" associated with vasomotor disturbance. Cured by faradism and reeducation.

latter overlap one another like the tiles of a roof —the commonly called "main d' accoucheur." Sometimes contracture with the hand in strong dorsiflexion on the wrist is seen, an unusual type in pure hysteria.

(*d*) The muscles are hyperexcitable to mechanical stimulation and respond by a sluggish contraction of large amplitude, especially where the limb is cold. Electrical excitability varies with vasomotor changes. There is usually changed excitability to faradism, and larger contractions are obtained than on the healthy side; there is never R. D.

(*e*) The reflexes are variable.

(*f*) Sensory loss is little more than can be accounted for by hypothermia of the skin.

(*g*) There is resistance to treatment by unaided suggestion, as contrasted with pure hysteria.

(*h*) The contracture does not disappear until the patient is deeply under a general anesthetic.

Some cases of physiopathic contracture take months to cure even by intensive methods of re-education. These more serious cases are noticed to be those with the most marked vasomotor changes.

6. *Paresis and Muscular Atrophy Associated with Joint Lesions.*—These cases are at once distinguished by the distribution of the amyotrophy. The wasting affects all the muscles which are used in movements of the affected joint, or joints. There is no R. D. or evidence of sensory loss.

7. *Contractures Associated with Painful Scars, etc.*—In this case the patient finds a certain movement painful because there is dragging upon a scar. He gradually assumes the position which is most comfortable for him and this may persist long after the original painful condition has been cured.

8. *Contractures due to Direct Injury to Muscle and Tendons.*—This type of deformity commonly follows upon large lacerated shell wounds. Masses of muscle may be shot away, or removed surgically because of gas gangrene. In less grave damage the healing process creates fibrous adhesions between the supporting tissues and muscle or tendon, thus hampering muscle activity.

One result of fibrosis in muscle is a deformity of joint axis due to unequal pull of synergic groups. A wound in the muscles of the calf of the leg will produce a "drop foot" by shortening of the muscles during scar consolidation. A glance at the local condition is enough for the diagnosis of this form of "drop foot." Testing by faradic current is useful to distinguish divided or adherent muscle or tendon from true paralysis.

9. *Purely Functional Cases Due to Bad Muscle Habit,* or *Incoordination of Muscles formerly Paralyzed.*—These form a large ill-defined group associated with various local causes. The faradic test quickly proves the absence of organic paralysis in the affected motor apparatus.

10. *Chronic Tetanus.*—One meets with rare cases of chronic tetanus which might be mistaken for hysteria or "reflex contracture." In these cases there are definite painful local spasms which are provoked by manipulation, etc. There is usually some degree of tonic spasm in the muscles of the jaw which is persistent even when the other local spasms relax. This fact is in direct contrast to the variable spasm of hysteria. The tendon jerks and the faradic excitability are exaggerated.

Differential Diagnosis.—Before any rational plan of treatment can be applied in a case of suspected nerve injury we should be in possession of the following information:

1. The anatomical position of the lesion.

2. Whether wholly organic in nature, wholly "functional," pithiatic (hysterical), "reflex" (physiopathic), or a combined functional-organic lesion.

3. The exact mechanism which is acting to produce any of the above conditions. The characteristic features of each type of lesion have been sufficiently outlined to enable all the above essential facts to be collected. It remains then, to form an idea as to what the future progress is likely to be, so that appropriate treatment can be adopted.

General Outline of Treatment.—The treatment adopted will be either surgical repair of the nerve, or simply suitable splinting combined with physiotherapy and electrical treatment. This latter course is adopted so long as the nerve is making satisfactory progress in regeneration by natural growth and repair.

In any case, after repair of nerves an early return to the electrical department, and next to warm baths and massage is desirable. We do not believe that massage or electrical treatment hastens the downgrowth of nerve fibers directly. The massage, movements, and electrical treatment are merely to keep up the local nutrition and improve the circulation of blood in a part where there is vasomotor paralysis.

Heat.—Head and others have noticed that cold winter weather retards regeneration of peripheral nerves. We have repeatedly noticed that cases treated without special attention to warmth recover more slowly than cases carefully clothed and subjected to artificial warmth. A warm equable climate would seem the best for regeneration after nerve injury. We have used warm water, both still and in "swirl baths."

Hot-air cabinets heated by electricity are good. This form of heat is easily regulated. A novelty of the 2nd Northern General Hospital is the warm bath of liquid paraffin wax. These baths are heated by electricity and kept at certain steady temperatures. There are baths containing wax which becomes liquid at a comparatively low temperature and others in which wax of higher melting point is used. The nerve injuries take no harm in wax at a temperature of 40° Centigrade. The stiff joints and other cases without anesthetic skin benefit by immersion in wax baths at much higher temperatures than the patient could bear in a water bath. The reason why the higher temperatures are not painful is that a thin layer of wax solidifies on the limb immediately it enters the bath and this acts in some measure as a protecting influence against the heat. The patients are enthusiastic about the paraffin wax baths, and there is no doubt but that the limbs so warmed keep warm for fully four hours afterwards.

It is almost unnecessary to utter a warning against the use of hot or even moderately hot baths in cases where "trophic burns" are likely to occur.

Electricity.—As to electrical treatment, we have found the most useful methods to be:

1. Surging faradism for weak and atrophic muscles which have retained their excitability to this current.

2. Constant current without interruptions in the early days after surgical repair. This current may be used for ionization with chlorine or iodide ions, especially for superficial scar tissue.

3. A constant current interrupted abruptly at regular intervals to cause contractions in the paralyzed muscles. It is better to insist that the masseuse use a small button electrode over each muscle in turn, so that each muscle has at least eighteen or twenty contractions at every treatment. If treatment of individual muscles be not insisted upon it is quite commonly found that some are neglected, and eventually degenerate into fibrous tissue.

4. Combined galvanofaradism is useful for cases that have recovered near to the point of restoration of voluntary movement in the affected muscles.

5. The local application of the medical diathermic current has been found to be of value in cases where vasomotor derangements are a prominent feature. Diathermy does not as a rule cure pain in peripheral nerve damage. The vascularization and absorption of scar tissue, which is alleged to be assisted by diathermy, has not occurred in many of our cases. All electrical treatment should be given by carefully trained masseuses. A good knowledge of anatomy and a three months course of training in the theory and practice of simple electrotherapeutics are essential to produce a reliable masseuse for work in the electrical department. Unskilled work is useless, and may do more harm than good to cases of peripheral nerve injury.

Massage.—Massage requires a skilled worker of even longer training and experience, than electrotherapy; unless constant supervision by a medical officer be at hand. In the early days after nerve suture, treatment should be limited to peripheral joint movements, especially those of the hand, and to deep work upon muscles situated some distance away from the operation scar. Gentle effleurage over the site of injury follows in about a fortnight, and from this date until the return of deep sensibility deep work for all muscles and daily movements of all joints should be practised. Where splints are worn it is especially important that all this work should be done in the most careful and painstaking way. Paralyzed muscles should not be forcibly stretched beyond their subnormal range. It must be remembered that their tone is gone, and their normal defense mechanism is temporarily out of action. Too forcible passive movements may lead to trauma and subsequent fibrosis. When the deep sensations return the patients experience unpleasant "pins and needles" when deep massage is carried out. In cases where regeneration is advanced it should be remembered that the patient will have exaggerated sensations to painful stimuli, and will experience most unpleasant sensations when manipulations are carried out which do not cause pain on the healthy side. As recovery proceeds it is good practice gradually to diminish deep massage, and to substitute surface work and put in more time at reeducation movements. The moment at length arrives when all massage should be stopped.

The patient will complete his cure by voluntary movements in the gymnasium and curative workshops, where special exercises are planned for him.

For the ideal result the patient should remain under supervision until there is complete motor recovery in every muscle. This is especially true where the upper extremity is involved.

Economically it is the soundest business for the individual, and for the State, to get a perfect result in a young man if this be possible, even though it take a long time to obtain. An imperfect cure makes a man face difficulties in finding employment, and results in the permanent charge to the State of an unproductive and subsidized citizen.

5 Park Square.

Medicolegal Notes.

Cross-Examination of Medical Experts.—In an action against a physician for failure to properly diagnose a fractured forearm, an expert had testified that proper practice would have required the use of the *x*-ray. During the expert's cross-examination by the defendant an offer was made to show by one of the expert's patients present in court that he had treated this patient without resort to the *x*-ray. The purpose was to discredit his testimony. The court sustained the plaintiff's objection to the introduction of this evidence. On appeal this was held to be correct. To have permitted this would have involved an inquiry into the character of this patient's injury, the diagnosis made and the treatment given, and practically opened up an investigation upon a collateral matter much the same as was being investigated in the case itself. The witness testified that he had treated patients with dislocated and fractured forearms "without subjecting the member to the *x*-ray process." He also testified that in case of "pure dislocation" the *x*-ray was not essential. Having had these answers it was held not error to rule against exhibiting the witness' patients.—McCollum v. Barr (Cal.), 176 Pac. 463.

Expert Opinion Based on Excluded X-Ray Photograph.—In an action for an injury consisting of a fracture in the shoulder joint there was admitted in evidence, over objection, an *x*-ray photograph, without any proof that it was genuine, or was a correct representation of the plaintiff's injured arm. While the photograph was not exhibited to the jury, the plaintiff's medical witness described to the jury what the photograph showed, and testified that, although he had been unable by physical examination to determine more than one fracture, the photograph showed a double fracture. Subsequently in the case it was conceded that the exhibit was incompetent, and it was withdrawn, and the jury were instructed to disregard it; but the defendant's counsel, believing that the evidence could not be disregarded by the jury, asked for a mistrial, which was refused. On appeal it was held that this was, under the circumstances of the case, prejudicial error. The plaintiff's doctor had testified as to the conditions flowing from two fractures to the humerus, and to their permanency. It is well settled that an expert witness may not draw inferences or state conclusions from the testimony of other witnesses. Furthermore, there was no doubt but that the doctor's testimony as to the accident being a competent producing cause for the injuries described by him, and as to the permanent effects of the injuries, was based largely upon the excluded *x*-ray photograph.—Walsh v. Frankenthaler, New York Appellate Division, 173 N. Y. Supp. 764.

X-Rays and Workmen's Compensation.—The Nebraska Supreme Court holds that in the present state of the science of *x*-ray examinations and *x*-ray photographs of the person there appears to be no reason why such examination or photograph should not be permitted by a claimant for compensation under the Employers' Liability Act, upon request by the employer or insurer, unless the request is shown to be unreasonable. But a claimant under the act cannot be denied a recovery because of a refusal to submit to an *x*-ray examination or to have an *x*-ray photograph taken of the person where the uncontradicted evidence shows that neither was necessary.—U. S. Fidelity etc., Co. v. Wickline (Neb.), 170 N. W. 193.

MEDICAL RECORD.

FUNCTIONAL RENAL CHANGES IN GYNECOLOGY.

THE procedures of examination of the renal functions should enter the domain of surgery and gynecology as a part of the general examination of the patient, as both surgical and gynecological affections are frequently complicated by renal disturbances. Were this done many untoward postoperative results might be avoided. From the viewpoint of the prognosis and operative indications much may be gleaned from a urological examination, such as a dilatation of the ureters and renal pelvis, which in itself would be an indication for hysterectomy for the removal of fibroid growths producing pressure on one or both ureters. The search for edema and determination of the blood-pressure will likewise give us data of the greatest value in gynecological cases, not merely from the viewpoint of chloride excretion, but from that of hydrochloride excretion as well, since both these functions usually go hand in hand and when disturbed produce edema and increased blood-pressure.

Renal lesions secondary to pelvic neoplasms, assume a peculiar type, while in other cases the possibility of a previously existing renal sclerosis and of lesions due to local conditions must be considered. It is not enough to detect renal lesions in gynecology, but we should also be able to attribute them to the pelvic lesion. The age of the patient demands consideration, because in young women infection and the exogenous and endogenous intoxications have not had the time to produce renal damage or the more or less advanced lesions of chronic nephritis. A carefully taken anamnesis may show the minor signs of brightism were absent before the advent of the genital affection, and, consequently, the probability of a preexisting renal sclerosis can be eliminated. But in doubtful cases one must be able to affirm or not the presence of renal changes dependent upon a pelvic tumor. If these changes are really due to ureteral compression from a uterine or ovarian growth, it would seem extraordinary that the functional renal disturbances should manifest themselves with equal intensity in both kidneys. Catheterization of the ureters will here find a legitimate indication.

It may well be objected that a difference in the functional value between the two kidneys is not sufficient evidence for eliminating some general cause, because of two kidneys the seat of an interstitial nephritis, it may be supposed *a priori* that the sclerosis may predominate in one, producing a more considerable deficit on that side, and this unquestionably is often the case. It is clear that the difference noted must be proved not to be due to a lesion belonging to that particular kidney, such as a neoplasm, tuberculosis, and, above all, to a movable kidney, so common in women. After catheterization of the ureters the urines are to be collected for two hours, a sample being taken every half hour. At the end of the first thirty minutes the patient is given three glasses of Contrexéville water in order to realize an experimental polyuria, and, before commencing the test, a hypodermic injection of phlorizine may be given and its elimination estimated in each of the half-hour samples of urine.

In subjects with chronic nephritis it would seem that the morbid process, having involved both glands at the same time, the pathological changes should offer the same characters in both kidneys, and the difference between the two urines should be very slight. This is true in many cases, but the total action will be found disturbed, although the functions of the two kidneys will be carried out equally. Consequently, in a general way, it may be said that in renal sclerosis due to some general cause, it is probable that both kidneys offer lesions of about equal intensity. However, frequently differences between the two urines will be noted which, in the majority of cases, are made manifest by the following characters of the urine from each kidney. The volume will be greater on one side, with a more marked concentration of the urea and chlorides on the other, the corresponding kidney being both quantitatively and qualitatively superior to its fellow. A fact worthy of remark is that the various functions are not parallel. The kidney with diminished functions may very likely manifest a marked change in one of its functions. By the sugar elimination it will be ascertained if the phlorizine test gives results which agree with those furnished by the analysis of the separated urines.

STATISTICS OF PRIVATE PRACTICE.

EVERY physician, whether novice or established man, should, if in general practice, keep some sort of analytical records of his patients which could be published for the benefit of the younger men. Such reports would, of course, be anonymous and beyond identification with actual personages. This is true especially of office business. It is frequently said by novices that practice is very different from what they had expected. They had looked forward to treating pneumonias, typhoid fevers, and fractures, but, instead, soon learned that nine patients out of ten had nothing the matter with them. If the ninety per cent. were analyzed the re-

port would make most interesting reading. There would be found the young mother with her first baby, the youth who had been reading the quack almanac, the subject with palpitation of the heart, the middle-aged man whose unpleasant feelings could be traced to overfeeding and underexercise, the person with brick-dust sediment in the urine, the woman who thinks she will lose her hair, and so on through the usual gamut. Special types of visitors come on more or less sinister errands—the newly married man who does not want children, the woman who wants gestation interrupted, the female adventurer who is of several distinct types, the man who schemes for advice favorable for fornication, the man in search of information which may be put to unlawful uses, etc., etc. Not one of these is a legitimate patient, although some of them may go through the form of stating some symptom and asking for advice.

Of actual ailing subjects some show a pronounced mental state which dominates the physical condition. They come to the office badly frightened and their tension begins to relax as soon as they are able to take their turn. The wearing suspense is now over. They find that they are in no serious or immediate danger, and with the mental state readjusted they cease to worry and probably will not even keep their next appointment. They can never again be frightened so thoroughly over their own condition. It is clearly bad for these patients to reassure them too quickly and thoroughly when they have organic or other serious disease, for we deprive them of a powerful conservative motif, that of a wholesome distrust.

The patient is well represented numerically who comes as a result of a conflict between need of professional services and dread of expense, interruption of business, the necessary publicity, etc. When some little happening tips the beam the right way, he comes, and often too late. The man, or more likely woman who knows herself to be ill but does not present herself until some alarming symptom develops is only too common.

The man who calls with the indifference of one who seeks to engage a plumber or other mechanic, simply because he regards his body as of as much importance as his house and in both cases takes time by the forelock is not so common as he should be. The man who wishes you to give him a complete examination and tell him the exact truth may be paired off with him who resents attention to his body at large and wants treatment for one ailment. The patient who wishes a guarantee of cure or who will deposit a sum of money in the bank for the physician to draw on when a cure is established should be noted as one of a general class who are financially unsatisfactory in various ways.

By analyzing one's material in this fashion for a term of years the most interesting tabulation could be prepared. There would result extensive types and rare ones, some patients would figure in more than one classification and the figures as to the personality of the patient could be offset by figures which sum up the diseases according to the diagnosis. The ancient student who rode for years with his preceptor and who learned the disease pedigrees of entire families as well as family peculiarities of behavior had a great advantage over the modern beginner and his work was largely cut out for him. An analysis of his practice would perhaps have taught him and his confreres little. Today the beginner who settles among strangers should find this custom of much value for his own guidance, and it would be still more useful for those who are to follow him.

TREATMENT OF ACUTE RHEUMATIC MYOCARDITIS.

THE localization in the myocardium during acute articular rheumatism is first of all to be guarded against by the exhibition of sodium salicylate, but since this medicament possesses a depressive action on the cardiac muscle, the dose of four grams daily should not be exceeded. When any suspicion of myocarditis exists, absolute rest in bed must be enjoined, even when the articular phenomena have subsided.

The partisans of the pathogenic theory emitted by Lees and others, namely, that the cardiac muscle is morbidly changed by the action of a substance similar to lactic acid, advise a prophylactic alkaline medication. But, regardless of all measures employed, myocarditis will occur, in which case there are three indications to fulfill, viz., (1) to control the cardia erethism; (2) to avoid all fatigue of the muscle, and (3) to act on the rheumatismal infection. The cardiac erethism may be controlled by the application of ice-bags to the precordial region, while pain may be successfully overcome by judicious revulsion, dry cupping, leeches, or even the use of the actual cautery, if required. This treatment is too much neglected in America, but the results obtained by the French school are sufficiently demonstrative to speak in its favor.

To prevent cardiac fatigue absolute rest is essential, while the action of the myocardium can be reinforced by cardiac tonics. Digitalis should be employed with extreme caution because, as Merklen has shown, this very valuable drug is contraindicated when there is marked dilatation of the right heart. Caffeine is the medicament *par excellence* of acute myocarditis and is better given subcutaneously when a rapid and intense action is desired. When the myocardium commences to flag, still more active measures must be resorted to, such as hypodermics of ether, camphorated oil, sparteine sulphate, or strychnine, while champagne and tincture of cinnamon are useful tonics during the latter phases of the process.

Theoretically, the rheumatismal infection should be treated with sodium salicylate, but on account of its depressive action on the heart it must be prescribed with great care. Many competent writers have even maintained that the salicylates favor localization of the process in the heart and, therefore, they may be advantageously replaced by salicin,

which has little or no deleterious cardiac effect. To favor the elimination of the rheumatic toxin a milk diet, diuretic drinks, and mild purgatives are indicated.

Convalescence is a period replete with danger. The patient should remain in bed for some weeks after all the phenomena of cardiac asthenia have disappeared. When the patient is up and about he should avoid both alcohol and tobacco for some time, likewise all violent exercise and athletics, and the physician should examine the heart from time to time in order to appreciate the condition of the myocardium, a bit of prudence often disregarded by both the patient and his medical attendant.

THE DISCUSSION FIEND.

Medical societies are composed of two sets of members, those who attend regularly and those who attend semi-annually. This is not a purposely heightened statement, but a calm representation of the facts, as the secretary of any society will testify. For the busy practitioner who sacrifices part of his all too little recreation time to attend the meetings of his local society we have nothing but praise. But it is toward a certain genus, one or more specimens of which are found in every medical society, that our remarks are directed. This is the discussion fiend. It is extremely embarrassing to the physician who has spent a great deal of time and trouble preparing a paper to have the usual request for discussion followed by a blank silence. The essayist cannot help but feel either that his paper has lacked interest or that he has made such egregious blunders that his colleagues refrain from alluding to them through delicacy. But on the other hand there is almost sure to be a number of more or less apposite remarks by the discussion fiend.

This individual may be a general practitioner and as such licensed by courtesy to give an opinion on all medical matters, but even if he is a specialist he does not confine his remarks to papers dealing with his branch. By no means! The discussion fiend discusses everything. Should the paper in question deal with his own specialty he is in his glory. If it describes an exceedingly rare case, he has seen a score, or a hundred—or as many of them as needed—in his own practice. He refers largely and easily to European authorities; he speaks of literature of the subject with an air of careless familiarity; he alludes to So-and-So of London, Blank of Vienna, and M. X. of Paris as if they were old cronies of his. If he has taken post-graduate work here or abroad, this is always alluded to, whether it has any relevancy to the subject in hand or not. Nor does he hesitate to drag in mention of cases referred to him. The proportion of sheer delight in talking to the amount of ill-concealed display of wares varies in different persons, but usually both motives are found.

The discussion fiend is frequently an omnivorous reader with a retentive memory. Happening to run across an allusion to a new form of treatment in a foreign medical journal he makes a mental note of it and at the earliest opportunity flashes a casual allusion to it before the eyes of his colleagues. If he reads that a certain form of treatment is beginning to be abandoned, he will state that for some time now he has given up this treatment and he finds that others are just swinging into line.

The only remedy for a discussion fiend is to adopt—and enforce—a limited discussion law. The president of a society has the authority to remonstrate with a speaker when his discussion grows unduly irrelevant or prolix and he should exercise this prerogative. By so doing he will earn the heartfelt gratitude of his fellow members.

Tuberculosis in an Insane Hospital.

It is but one more illustration of the almost universally prevalent neglect of physical states which a patient has to endure once he enters an insane asylum that but little has been done to prevent and cure pulmonary tuberculosis arising in these institutions. To be sure, it is very common nowadays to find special buildings for consumptives in insane hospitals and in many of the more modern institutions they may be such admirably constructed ones, as the improved Loomis shack. But if we investigate somewhat deeper it is the rule to find that these beautifully adapted buildings are but wards for consumptives to die in. The diagnosis is made only when the condition has advanced so far that the patient is bedridden, his sputum full of bacilli, and he is literally dying. In the *American Journal of Insanity* for January, 1919, Dr. S. A. Silk calls attention to this state of affairs. The remedy he suggests is an active tuberculosis service directed by a member of the staff who has had the requisite experience, or who is willing to interest himself in the subject. A large building, surrounded by porches, should be set aside for cases which are not as yet "open," this to be called the "preventorium." Here cases might be given approved dietetic and hygienic treatment and their progress carefully watched. The open cases should be kept in the regular tuberculosis cottages, such as the improved Loomis shack. As they improved they could be transferred back to the wards via the preventorium. In this way two great objects are accomplished: First, the uninfected patients in the regular wards would not run the risk of acquiring tuberculosis, as they do now so greatly. Second, a mental patient developing tuberculosis would be diagnosed in time and given a splendid chance of recovery. Too often now, owing to many circumstances, the most obvious of which is the difficulty of eliciting subjective symptoms from a patient of this sort, tuberculosis goes on until it is beyond recovery; the case is then discovered, called "incipient" and placed in a tuberculosis cottage, where the patient rapidly grows worse and dies. Let us then remove this discredit to psychiatric hospitals—one of the few now left—and by so doing we shall remove one more reason for dreading these hospitals and promote voluntary admissions with their attendant benefit to the mental hygiene of the community.

Sporotrichosic Arthritides.

In 1909, Beurmann, the leading authority on the sporotrichoses, announced the opinion that in virtue of the existence of osseous lesions of this origin joint lesions would also come to light. This prophecy was almost immediately realized in the report of three cases, and soon after several investigators reported the existence of sporotrichosic synovitis of various types. In one case both lesions coexisted in one subject. Aimes, in the *Gazette des hôpitaux* for April 26, has collected notes of 7 additional cases, and announces that in at least two the joint was implicated; or in other words, something more than the synovial membranes or sheaths was involved. Briefly stated, this affection is one which ordinarily would pass for a tuberculous osteoarthritis, especially when it occurs as an isolated affection. As part of a general sporotrichosis it would be associated with subcutaneous gummata and ulcers, and perhaps bone lesions. Occurring only in one joint, the lesion would have to be termed primary. Experience has shown that the diagnosis is more readily made in the multiple cases, while the primary cases have presented much difficulty in diagnosis. In such cases, indeed, no one would even think of sporotrichosis; and, in fact, one case is on record in which a leg with this knee made such a bad impression that it was at once amputated; and other similar cases have no doubt existed. In the known case a sporotrichosic gumma appeared later and showed the error of diagnosis. The enlargement of the knee may be rapid or insidious. Several cases were typical "white swellings," with fistulæ. The knee is the joint involved in the majority of cases. Another articulation mentioned is the sternoclavicular. The practical importance in citing the sporotrichosic white swelling as a disease entity consists in the fact that a knowledge of it may be able to save a limb now and then. The diagnosis is readily made by scrappings and culture, and the affection yields to iodine medication. The treatment is quite efficacious, but does not prevent prompt relapses *in situ* or in another joint.

News of the Week.

Hospitals Planned for Queens.—Memorial Hospital buildings in honor of the soldiers of the Borough of Queens, New York, who lost their lives in France will be erected at a cost of $500,000. The Citizens' Committee of that borough which has charge of the work proposes to raise the funds for these buildings by a public drive throughout the borough. The buildings will be added to St. Mary's and the Jamaica Hospitals. They will be equipped with 100 beds each and will have in addition laboratories, clinics, ambulances, and all other modern hospital facilities.

Bill to Restrict Vivisection.—Senator Myers of Montana announces his intention of introducing a bill into Congress which will narrowly restrict the practice of vivisection in the District of Columbia. He declares that unregulated vivisection means its extensive practice merely to satisfy "wanton and idle" curiosity rather than to serve scientific ends, and expresses the hope that public sentiment will soon demand national legislation to curb its abuses.

Red Cross Relief Work Increases.—According to a report given out at the headquarters of the Atlantic Division of the American Red Cross, on May 19, more than 6,000,000 finished articles for distribution among European refugees and convalescent American soldiers have been received in the division warehouse since November 1, 1918. Of the total collection large quantities have been in the form of hospital supplies and accessories for the hospitals in the metropolitan district which have received wounded American soldiers. Figures for the six months period show that the Atlantic Division chapters supplied 829,439 hospital garments, 693,336 medical and surgical articles, and 3,881,383 surgical dressings. In April the division distributed 86,647 articles of comfort to soldiers and sailors in addition to those supplied to the hospitals.

Charitable Gifts and Bequests.—Under the will of Mrs. Mary W. Almon, the Cambridge (Mass.) Hospital will receive $10,000 for a memorial of Elizabeth Almon Cudworth and Elizabeth Derby Almon, and the Massachusetts General Hospital of Boston will receive $5,000.

Discuss Nursing Situation.—The Public Health Committee of the New York State Reconstruction Committee met in the New York Academy of Medicine on May 19 for the purpose of discussing the nursing situation. The speakers were Dr. Henry Dwight Chapin, Health Commissioner Royal S. Copeland, and Dr. Matthias Nicoll, Jr. Dr. Chapin recommended shorter periods of training in a hospital, with a large experience in the bedside care of the sick as sufficient to fit a large number of women to care for most cases of illness. He advocated one year's training for aids to nurses. For this class of nurses a high school education he considered unnecessary. Dr. Copeland called attention to the fact that the present situation in the New York Hospitals is such that there is an annual deficit of $1,000,000 and the hospitals rob the nurses and make them do menial work to make up for this when they could spend their time more profitably doing other things. Dr. Nicoll told of the great need for more public health nurses and advocated a two years' course which would prepare women for this work.

Clinics for Foreign Visitors.—The Committee in charge of receiving and entertaining the foreign delegates to the American Medical Association meeting during their stay in New York for the first week in June have arranged a series of clinics for Wednesday, June 4, to be held at the following hospitals from 9 to 12 A. M. and from 2 to 5 P. M.: Roosevelt, St. Luke's, Bellevue, Presbyterian, New York, St. Francis', St. Vincent's, Post-Graduate, French, Hospital for Ruptured and Crippled, N. Y. Eye and Ear Infirmary, Manhattan Nose and Throat, Lying-In, Hahnemann, Flower, Woman's; Cornell Medical College, College of Physicians and Surgeons, University and Bellevue Medical College, Fordham Medical College, Long Island Medical College and Rockefeller Institute. Visiting physicians and members of the American Medical Association are cordially invited to attend these clinics.

Dinner for Visiting Delegates.—It is announced that a dinner will be given at the Hotel Commodore, New York, on Thursday, June 5, in honor of foreign delegates to the annual meeting of the American Medical Association. The tickets, which will be ten dollars per plate, can be obtained from the secretary of the committee, Dr. John J. MacPhee, 853 Seventh Avenue.

Opposition to Compulsory Health Insurance.—At a meeting of the social insurance department of the National Civic Federation, held in this city last Saturday under the presidency of Warren S. Stone, grand chief of the Brotherhood of Locomotive Engineers, strong objection to compulsory health insurance was expressed by most of the speakers. Attention was called to the failure of the system of compulsory insurance in England and Germany, in which countries it had fostered an increase in malignering. It was proposed to send a commission to England to gather facts for the information of legislators and employers now confused by propaganda disseminated by social reformers who have undertaken to promote compulsory health insurance.

Hospitals for Near East.—To meet the great need in Palestine and Serbia, the American Women's Hospitals is sending a fully equipped hospital to each of these countries. Included in each unit is a mobile hospital of fifty beds, sixteen motor ambulances, with drivers, in addition to the requisite number of doctors, and nurses. A fully equipped unit which reached Serbia a short time ago reports an overwhelming amount of work and great need of additional helpers. Dr. Agnes Goldman of New York who has been working in Serbia has just returned to this country.

Drug Addicts May be Identified.—Dr. Royal S. Copeland, Health Commissioner of New York, has been advised by William P. Burr, Corporation Counsel, that the Board of Health has the power to make certain changes in the Sanitary Code, relating to the control, identification, and classification of drug addicts. Upon the receipt of this notice Dr. Copeland announced his intention of going ahead immediately with the Health Department's drug addiction program. The form of identification cards to be used has already been determined upon and arrangements are being made with the Police Department concerning the method of registering and identifying addicts.

Plans for Physical Training of Boys.—At a recent meeting of the Physical Education Society of New York, it was announced that physical training will be provided for all boys in this State between the ages of 16 and 18 years, who are included in the universal military training law. It is estimated that the military law affects some 220,000 boys, while only 20,000 are attending school where there are facilities for physical training. Under a plan which provides for the reorganization of the national military program, which was outlined by Dr. Thomas A. Storey, State Inspector of Physical Training, it is proposed to reach the remaining 200,000 and drill them in beneficial athletics, games, and gymnastics.

Colonel William J. Mayo of Rochester, Minn., has been awarded the Distinguished Service Medal by the War Department.

Red Cross Nurses Decorated.—Miss Jane Jeffery of New York, an American Red Cross nurse, has been awarded the Distinguished Service Cross for her courageous conduct during a German air raid on the American Red Cross Hospital at Jouy-sur-Morin, when though wounded severely herself she continued to render assistance to others. The Distinguished Service Medal has been posthumously awarded to Miss Jane Delano, head of the Red Cross Nursing Service in France, who died there last month.

Dr. Samuel J. Kopetzky has returned from duty with the American Expeditionary Forces and has resumed his practice at 51 West 73d Street, New York City.

Dr. Charles Halpin Nammack has returned from service in France and has resumed his practice at 379 Park Avenue, New York City.

Gifts and Bequests.—Under the will of Edward A. Kerbs, the Hebrew Orphan Asylum of New York City is to receive a bequest of $15,000 and the Trudeau Sanitarium at Saranac, N. Y., is to receive $50,000. The will provides that if the daughter dies without issue the principal of the estate is to be used to establish the Kerbs Hospital for Tuberculous Diseases.

Position Open for Psychiatrist.—The Civil Service Commission of the State of New York announces a vacancy for a psychiatrist, man or woman, on the State Commission for Feeble-Minded at a salary of $5,000. Applicants for this position must be licensed practitioners of medicine in good standing and have had at least ten years in the actual practice of their profession. They must also have had special experience and training in the treatment and care of the insane or mental defectives such as might be obtained in State institutions. During their sreviee in a State Hospital they should have held positions of responsibility affording executive and clinical experience. No written examination will be given, but candidates will be rated on their education, experience, and personal qualifications. The examination will be held on June 28. For application forms address a postal card to the State Civil Service Commission, Albany, N. Y.

The American Proctological Society will hold its twentieth annual meeting at the Hotel Chalfonte, Atlantic City, June 7-9, 1919, under the presidency of Dr. Jerome K. Lynch of New York City. The Secretary is Dr. Collier F. Martin, 601 Professional Building, Philadelphia, Pa.

The American Neurological Association will hold its forty-fifth annual meeting in Atlantic City, June 16, 17, and 18, 1919, under the presidency of Dr. James McBride of Pasadena, Cal. The headquarters of the association will be the Hotel Brighton. Communications relating to the meeting may be addressed to the Secretary, Dr. Frederick Tilney, 22 East 63d Street, New York City.

Dr. George E. Hetherington, of Piqua was elected president of the Homeopathic Medical Society of Ohio at the annual meeting of the Society held in Columbus on May 14.

Dr. Augustus W. Shea of Nashua, was elected

president of the New Hampshire State Medical Society at its annual meeting held in Concord, May 15.

Dr. Elmer E. Liggett of Oswego was elected president of the Kansas State Medical Society at its annual meeting held in Ottawa on May 8.

Obituary Notes.—Dr. ALEXANDER LYLE died at his home in New York, after a rather protracted illness, on May 23, aged 53 years. He was a graduate of the medical department of New York University, in 1888. He served an internship at the City Hospital, and immediately took up the practice of surgery. Early in his professional career he became associated with Dr. John A. Wyeth at the Polyclinic Medical School and Hospital, becoming professor of surgery in that institution in 1908. Shortly after its organization he became a member of the American College of Surgeons. He was a member of the New York Academy of Medicine, the American Medical Association, the New York County Medical Society, and the Lenox Medical Society. For several years he had been attending surgeon at the City Hospital, Blackwell's Island.

Dr. JOHN HERMAN EDEN, a graduate of Yale Medical School, in 1874, and formerly connected with the staff of Bellevue Hospital, died of heart disease at his home in Little Neck, Long Island, N. Y., on May 19, aged 69 years.

Dr. HERBERT M. BISHOP, a graduate of Yale University Medical School, in 1865, died at his home in Los Angeles on April 23, aged 75 years. He served as surgeon with the First Connecticut Cavalry during the Civil War, and was a former president of the California State Homeopathic Society and a member of the American Homeopathic Society.

Dr. DAVID WILEY died at Salem, N. J., of heart disease on April 30, at the age of 71 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1870.

Dr. BENJAMIN B. REATH died of pneumonia at Philadelphia on May 6, at the age of 56 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1887, and had practised there continuously since that year

Dr. F. HARVEY DAY died at Wilmington, Del., on May 8, at the age of 56 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1885.

Dr. SAMUEL HENDRICKSON, a graduate of the College of Physicians and Surgeons, in 1875, and for thirty-seven years a practising physician of Jamaica, L. I., died suddenly of heart disease on May 20, aged 69 years.

Dr. HENRY DAVIDSON FRY, a graduate of the University of Maryland School of Medicine, in 1876, died at his home in Washington, after a long illness, on May 12, aged 66 years. He was for many years professor of obstetrics at the Georgetown University, and on his retirement in 1917 was made professor emeritus. He supervised the erection and equipment of the Riggs Maternity Memorial Building in Georgetown, and was well known as a writer on his specialty.

Dr. HEBER JOHN RICHARDS, a graduate of Bellevue Hospital Medical College, and a pioneer practitioner of Utah, died at his home in Provo, on May 12, aged 79 years.

Correspondence.

THE IODINE URINE TEST FOR ACIDOSIS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—It appears from letters which I have received that I did not make myself wholly clear in my article of March 8 regarding this test, hence if you can find space for this supplementary note it might help the general understanding of what I find to be as useful a test of acidosis in diabetes as the thermometer is of fever.

While it is true that normal urine has the property of decolorizing weak solutions of iodine, the increase in power to decolorize, shown by the urine of acidosis of diabetes mellitus and of pregnancy, is not due to uric acid, creatinine, etc., in increased percentage. Urines containing unusually high percentages of these constituents have been tested by the writer and found not to decolorize iodine to anywhere near the same extent as does the urine of acidosis. Moreover sugar is not the agent which accomplishes the decolorization. If a patient suffering with the acidosis of diabetes mellitus be fasted until just such a time as the sugar has left the urine, but before improvement from acidosis has had time to manifest itself, it will be found that the amount of urine necessary to decolorize the solution described in the MEDICAL RECORD for March 8 will be small, usually less than 10 c.c. Hence sugar did not cause the decolorization. Again if this same patient be kept under observation until, by cautious feeding, he has improved measurably, and until the uric acid, creatinine, etc., have increased in the urine, it will be found that the amount of urine needed to decolorize the iodine rises above 10 c.c., and keeps on rising until it is practically normal, that is above 20 c.c.

CLIFFORD MITCHELL, M.D.

25 E. WASHINGTON STREET, CHICAGO, ILL.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, April 30, 1919.

Reform in the R. A. M. C.; a Chance for the Scientific Worker.—This week there has quietly come into existence an alteration in the conditions of service in the Royal Army Medical Corps which constitutes the greatest reform that has taken place in that service for a generation. Moreover it is a reform of promise as well as of performance. Directorates in Pathology and in Hygiene have now been created within the Army Medical Department, the scheme permitting for specially selected men to rise through all ranks of the Army to Major-General *on the strength of their scientific work.* Hitherto, a few notable men being excepted, the rule in the R. A. M. C. has been that whatever a man's qualifications, tastes, or abilities, he must, at any rate on attaining the rank of Major, be prepared to go off into administrative work and leave his scientific duties to his juniors. If he preferred to remain working in Bacteriology, in Preventive Medicine and Hygiene, or in Tropical Diseases, for example, he could do so, but, except in extraordinarily fortunate circumstances for himself, he

would find that his devotion to science had cost him all chances of promotion in his service, promotion being reserved for the administrative billets. Conceive the waste of such an arrangement! Always young men were being taught, and well taught, how to become the scientific branch of their Corps, and, exactly as they had found their *métier*, precisely as they had become valuable advisers of officers, men, the Army, and indeed the nation, they were asked to choose between self-sacrifice or a career of superintending other people, of giving orders, of supervising hospitals and military establishments generally, in short, a career of what is called administration. How could the younger men be expected to preserve their interest in their scientific studies if such was the outcome? And how could their seniors be expected to remain in touch with the scientific developments in whose working out they no longer had any personal share? This now has all been changed, largely owing to the pertinacious, skilful and sympathetic work of Sir John Goodwin, Director General of the R. A. M. C., who has for a year been preparing his scheme of reform with the assistance of the two principal exponents of scientific work with the Corps, Sir William Leishman and Sir William Horrocks. It is certain that the possibility, and, for good workers, the probability of attaining to positions of proper trust and emolument by scientific work will much improve recruiting among the officers of the R. A. M. C.—that will be the immediate outcome of the new scheme; but there will almost certainly follow similar arrangements by which special medical service generally will receive higher consideration in the Corps. Not only is there in the work of the Army Medical Department scope for original labor and research in tropical disease, in Preventive Medicine, and in Bacteriology, but a vast clinical field is also open to these officers, and the specialist in medicine or surgery, in venereal disease or in ophthalmology has as much right as the sanitarian or bacteriologist to expect that his particular skill shall receive particular recognition; shall count, in short, to his credit in rank, pay, and pension. It is certain that these further developments will shortly follow, and it is to be hoped that all the improvements in the conditions of service in the R. A. M. C. will also find their analogues in the Indian Medical Service, though the identical scheme for the one cannot be expected to fit the varying circumstances of the other.

The Dogs Protection Bill.—The bill has procured a remarkable volume of protest from physiologists, who perceive its dangerous and illiberal nature; while the medical members of Parliament have given their colleagues in the House the reason for their opposition to the measure.

A War Memorial to the Officers and Men of the R. A. M. C.—The affairs of the R. A. M. Corps are bulking largely in public this week, and it is right that it should be so in what, it is hoped, may be the actual closing theses of the world war. For in that war no particular unit has played a more useful and devoted part. A scheme has now been promulgated for the erection of a memorial to the officers and men of all branches of the corps who have fallen in the war, and the following comprehensive committee have consented to serve, and have indeed already presented a report on the subject: *Chairman,* Lieutenant-General Sir Alfred Keogh, G.C.B., G.C.V.O., C.H., M.D., F.R.C.P.; *Vice-chairman,* Lieutenant-General Sir John Goodwin, K.C.B., C.M.G., D.S.O., K.H.S.; *Secretary,* Captain A. R. Wright, D.S.O.; *Regular Army,* Lieutenant-General Sir Arthur Sloggett, Kt., K.C.B., K.C.M.G., K.C.V.O., K.H.S., Lieutenant-General Sir Launcelotte Gubbins, K.C.B., M.V.O., Major-General S. Macdonald, C.B., C.M.G., K.H.P., Major-General Sir H. R. Whitehead, K.C.B., Major-General Sir W. G. Macpherson, K.C.M.G., C.B., Colonel C. R. Tyrrell, C.B., Colonel O. L. Robinson, C.M.G., K.HP., Brevot Colonel Sir E. Worthington, Knt., K.C.V.O., C.M.G., Major St. J. A. Maughan, D. S. O., Captain R. E. Todd, a sergeant-major, a staff-sergeant, and a private; *Territorial Force,* Major-General Sir Berkeley Moynihan, Knt., K.C.M.G., C.B., F.R.C.S., Colonel A. D. Sharp, C.B., C.M.G., F.R.C.S., Lieutenant-Colonel, A. M. Macintosh,, M.B., F.R.C.S., Major E. B. Waggett, D.S.O., Captain G. T. Willan, D.S.O.; *Special Reserve,* Lieutenant-Colonel A. A. Watson, D.S.O., Major S. G. McAllum, M.D., and Captain J. G. McCutcheon, M.B.; *Temporary Commissioned Officers,* Colonel Sir T. Crisp English, K.C.M.G., M.B., F.R.C.S., Major P. Turner, M.B., F.R.C.S, and Captain A. R. Owst, F.R.C.S.; *Consultants,* Major-General Sir George Makins, G.C.M.G., C.B., F.R.C.S., Major-General Sir Bertrand Dawson, G.C.V.O., C.B., M.D., Major-General Sir Anthony Bowlby, Knt., K.C.M.G., K.C.V.O. C.B., F.R.C.S., Brevet-Colonel Sir W. Hale White, K.B.E., M.D., and Sir Norman Moore, M.D., F.R. C.P., President Royal College of Physicians; *Ireland,* Colonel W. Taylor, M.B., F.R.C.S.; *Scotland,* Colonel H. M. W. Gray, C.B., C.M.G., F.R. C.S., and Colonel Sir H. Styles.

It will be seen that the committee contains representatives of the Regular, Territorial, Special Reserve and Temporary officers, as well as a few non-commissioned officers and distinguished physicians and surgeons, whose connection with the corps, is simply of a consultant character. The permanent memorial, or monument, will be erected on a central site in the metropolis, and it is recommended by the committee that replicas of it should also be placed in Edinburgh and Dublin. The number of officers of the corps who laid down their lives for their country is 560, while over 4000 men of other ranks were killed, or died in discharge of their duties. During the war 17,338 officers, and 179,711 men served in the corps.

The Director General of the Army Medical Service has published to-day the following recommendation of the committee, with a view to elicit subscriptions from the public, as well as from the medical profession, and having regard to the notoriously difficult, dangerous, and useful responsibilities discharged by the corps, it is probable that the sum of money needed, though a large one, will be promptly forthcoming: (1) That a permanent memorial or monument be erected in London, with, if possible, replicas in Dublin and Edinburgh. (2) That a fund be formed from which grants in aid be given to the families of officers, non-commissioned officers, and men of all branches of the Royal Army Medical Corps who have fallen

or been disabled in this war, or who may be in necessitous circumstances owing to the exigencies of military service. (3) That scholarships or memorial prizes for officers and men of the Royal Army Medical Corps be founded for research work. The Duke of Connaught, late Governor-General of Canada, is the new honorary chairman of the committee.

The Post Graduate Scheme for London and the Provinces.—The scheme for post graduate education with which the name of Sir William Osler is intimately connected has already been outlined in your columns. This week, at a meeting held at the house of the Royal Society of Medicine, the details of the scheme were approved of unanimously, though there were differences of opinion as to the preparatory part which it was proposed that London should play in the organization. It is almost inevitable that this should be so at first, but the various post-graduate organizations are to acquire complete independence and self-government under the scheme.

Honors for Service Men.—Canada, the oldest dominion in the Empire, has definitely pronounced against the principle of titles—hereditary or otherwise, but at home their bestowal is regarded as a convenient and extraordinarily cheap manner of rewarding public service. A long list of so-called "New Year Honors" has found its way into the *Gazette* this week, and among the names are five medical men, viz., Dr. Norman Moore, Mr. J. M. Cotterill, Dr. Edward Malins, Mr. C. S. Tomes and Dr. T. J. Verrall. Dr. Norman Moore, devoted historian of St. Bartholomew's Hospital and an authority on medical history and archæology, obtains the baronetcy that is almost traditionally attached to his important post of president of the Royal College of Physicians of London. The other four doctors receive knighthoods. Mr. Joseph Cotterill, a famous Scottish surgeon, was in his youth an eminent cricketer, and during the war has been commandant of the Edinburgh Military Hospital; Dr. Malins, a Birmingham obstetrician, has been a generous benefactor to projects of public utility; Dr. Verrall acted as Chairman of the Central Medicine War Committee throughout the valuable existence of that body; and Mr. Tomes is the dental authority on the General Medical Council, where he sits as a nominee of the Crown. Mr. Glyn-Jones, a pharmacist and secretary of the Proprietary Articles Trade Association, has also been knighted. A member of Parliament, he acts in the House of Commons as Parliamentary Secretary to the Pharmaceutical Society of Great Britain.

The Risk of Rabies; a Dog Landed in a Bag.—Only last week I surmised that the outbreak of rabies in the metropolitan area, and earlier in the south and west of England might have had origin in the smuggling over of pet dogs from infected districts on the Continent. This week a remarkable confirmation of this idea was received from the proceedings at the Croydon police court, when a captain in the Royal Air Force was convicted and fined for landing a fox-terrier surreptitiously on his return from Holland as a repatriated prisoner. The defense put up for this erring officer was that, having been out of England, he knew nothing of the Importation of Dogs Order, but the plea was rather a cynical one to make in face of the fact that the dog was smuggled through the port of entry in a handbag. Moreover, the officer's statement that the dog was worth a good deal of money showed a pecuniary motive for disregarding the public safety. It is well that a good deal of publicity was given to this case, as there are many members of the public who might be tempted to bring a dog into the country, feeling certain that their pet, at any rate, must be free from infection. The sooner the public understands that the law against the importation of dogs, framed in behalf of public safety, cannot be defied with impunity, the better chance there will be of the eradication of rabies.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

PARIS, April 20, 1919.

Sanitarians en Route to the Cannes Health Conference.—Several British and American specialists have arrived in Paris, on their way to Cannes, to participate in the International Conference of Red Cross Societies. Among them are Colonel S. Lyle Cummings, Dr. William H. Welch, Colonel F. F. Russell, Dr. Herman M. Biggs, Dr. E. R. Baldwin, Dr. Emmett Holt, Lieutenant Colonel Sir Ronald Ross, Dr. Samuel McClintock Hamill, and Dr. Fritz F. Talbot, Sir Arthur Newsholme of London, and Dr. Truby King of New Zealand.

Professor Roux, Professor Vidal, Dr. Edouard Rist, Dr. Bernard, Dr. Laveran, Dr. Millian, and Dr. Armand Delille will join the other delegates in preparing a programme of united action to relieve suffering and combat disease in the interest of all peoples.

The first week's sitting of the Committee of the "Big Five" Red Cross Societies has been entirely devoted to the consideration of the Central International Health Bureau, required to act as a linking-up agency for the Red Cross societies of the world. On Monday the Conference will devote itself to the consideration of the reports presented by various groups on venereal disease, nursing, preventive medicine, hygiene, tuberculosis, and malaria. One of the interesting personalities of the Conference is the eminent Frenchman, Dr. Edouard Rist, of the Service de Santé, who acts as interpreter. Most of the speeches are made in English, but the French, Italian, and Japanese delegates speak in French. Dr. Rist, at the conclusion of each speech, gets up and makes perfect translations. His English is a constant wonder to all who listen to him. Indeed, some of the delegates laughingly state that he improves their original remarks in translating.

The outstanding speeches at the conference were made by Sir Ronald Ross, Sir Robert Philip, Professor Roux of the Pasteur Institute, and Dr. Truby King of New Zealand. Sir Robert Philip regretted that it was not possible to distribute by means of the gramophone throughout the world some of the information discussed at the Conference. Professor Roux urged that the Central Red Cross Committee should become a center of stimulation for medical research for mankind. Sir Ronald Ross said that he regarded the formulation

of a combined scheme of sanitation as of great moment for the world and one which he had often thought of in the past. He made a forceful appeal for the provision of adequate means for research work by the central health body to be set up, and referred to the fact that his work had often been hampered through lack of funds. Dr. Truby King quoted Huxley as saying that science was merely "crystallized common sense" and what was needed was to tell the man in the street health facts in simple language. He referred to the appalling fact that half the inmates of our lunatic asylums were suffering from a disease introduced during the first nine months of their life, and he made an appeal that the great health crusade to be undertaken should concentrate on the children.

The American Committee for Syria and Armenia has sent a mission of 42 members, who have just landed at Beyrout. The object of the Committee is to open free dispensaries and assist the work of the Red Cross organizations.

Red Cross Relief for Poland.—A train of sixty cars carrying 2,000,000 francs ($400,000) worth of relief supply, and fifty physicians, nurses, and sanitary workers from the American and Polish Red Cross societies is on its way to the territory east of the River Bug, where the greatest suffering and destitution prevail as a result of typhus and hunger. Headquarters will be established at Brest-Litovsk. The train also carries 400 miles of telephone wire to be used in establishing communication between the units and the general headquarters of the American Red Cross Commission to Poland in Warsaw. The relief equipment also includes six field kitchens and disinfecting plants. The purpose ultimately is to turn over the whole health organization to the Polish National Red Cross.

The despatch of this relief train was found necessary through the investigating expedition recently sent out by the American Red Cross Commission to Poland. The American investigators found food supplies exceedingly scarce in the larger towns and utterly lacking in some isolated villages. The population in Eastern Poland has been reduced almost one-third by disease, hunger, and war emigration. Typhus is epidemic in almost all the small villages and smallpox is to be found in various sections. One-half the medical profession has been lost to the communities through the war, with the result that people have been left with an insufficient number of physicians and nurses.

3. The Maloney Method of Reeducation in the Treatment of Chorea.—Morris Grossman points out that for a clear understanding of the clinical entity known as chorea, which is more frequent in girls than in boys in the proportion of three to one, it is essential to limit the application of the term to a disturbance of the central nervous system characterized by sudden, rapid, widespread, seemingly involuntary movements, devoid of outward purpose, yet not wholly beyond the control of the will, and aggravated in excited, and moderated in tranquil states. The term minor chorea should be applied only to cases in which, with or without the occurrence of an infectious process or of an emotional crisis, these characteristic movements spontaneously begin, gradually becoming more conspicuous. There seem to be two types; one in which infection and emotional accidents are blamed, the other in which these factors are not implicated. There are also two types of patients; those who before the disease were notably restless and excitable, and those who did not differ markedly from the average child. In the latter, onset of the disease can often be traced to some infection; whereas in the former the disease more often dates from some emotional stress. Physical examination as a rule does not reveal any great change in the size of the muscles, although the tone may be slightly diminished. Superficial reflexes are usually present and sometimes unusually active on both sides; deep reflexes are normal as a rule, and sensation undisturbed. Pathologically neither gross nor microscopic lesions have been found in a sufficient number of cases to afford a definite structural foundation for the symptoms. The bacteriological findings suggest a clinical phenomenon resulting from the action of a bacterial toxin upon the cortical tissues. It would seem from evidence available that there is no distinct causal relationship between rheumatism, endocarditis, and chorea; there is, however, a close association in about 20 to 25 per cent. of cases. *Treatment:* Patient should be confined to bed during the acute stage. All mental and intellectual efforts should be avoided, and all emotional influences shunned. A competent nurse and a well ventilated room are of value, with bland diet and hydrotherapy in the form of tepid douches or packs. In severe cases continuous warm or tepid packs are of great benefit in soothing the patient. Bowels should be kept open and a mild saline given if necessary. A thorough course of salicylates should be given in cases with a rheumatic history; aspirin or salicylate of soda up to five-grain doses with ten grains of bicarbonate of soda should be given every four hours to a child of ten. If there is no history of rheumatism, arsenic in the form of Fowler's solution (diluted with half its bulk of distilled water in the case of a child of ten), or Donovan's solution may be given. The urine should be closely watched for albumin; diarrhea or puffiness of the eyes should be followed by immediate reduction of the arsenic or its temporary discontinuance. In cases with marked motor unrest, bromides in five-grain doses every four hours may be given by mouth. Salvarsan and neosalvarsan have been advocated on the assumption that chorea was a manifestation of syphilis; the author, however, believes that in the small proportion of cases in which syphilis was present, it was merely a coincidental condition. The subcutaneous injection of magnesium sulphate solution, the intravenous injection of dilute phenol solution, and the intraspinal injection of autoserum have all been tried. The author has found the rest or relaxation exercises described by Maloney of value in quieting the patient during the acute febrile period. The diaphragmatic breathing is of great value in inducing relaxation of the muscles. The patient is asked to take a deep breath using his diaphragm, restricting his thoracic movements, and at the height of inspiration to pause, then slowly and evenly expire, and again pause. This breathing soon tires the patient, so after ten or twelve of these deep respirations have been taken, the depth of inspiration and the pause are shortened until the patient is breathing, without effort, as in sleep. To relax the muscles, passive movements in which the muscles are alternately lengthened and shortened are employed. The muscles of the forehead, cheek, and jaw

are manipulated until wrinkling of the forehead and blinking of eyelids disappear and the muscular spasm is eliminated. Next a shoulder is relaxed, then an arm, a leg, and so on. After a part is relaxed, the parts previously treated should be briefly dealt with again in the order in which they were first relaxed. This is helpful in bringing the entire body into a state of relaxation. During the passive movements, the patient's attention should be directed to the control of the choreic twitchings; gradually this requires less and less effort, and soon complete and perfect relaxation is possible. When the temperature and pulse have been normal for several days and the limbs can be freely moved passively without rigidity or spasm, active movements may be begun. Simple movements—flexion, extension, adduction, and abduction of joints—should be regulated by a metronome. The patient next resists the movement, in order to increase the ability to maintain tonic contraction; and finally the movement is made against the resistance of the operator. When the patient is able, in the recumbent position, to perform normal movements, reeducation in maintaining the normal attitude may be commenced. Creeping on hands and knees, balancing and creeping on knees, and finally maintaining an erect attitude and progression. Changes should be made gradually and fatigue avoided, and rest exercises should be given alternately with active work. Toys and games are useful in helping patients to regain precision of movement; they also interest and amuse the patient. The aim of these exercises is to encourage freedom as well as precision of movement; incoordination is corrected and concentration with increased mental stability is thus promoted.

2. Theories Regarding Blood Pressure.—Harold W. Dana has had an opportunity of studying blood-pressure findings in a large number of army officers and candidates for commissions in the army, chiefly men over 30 years of age, medical officers being in a large majority. He states that the more he studies blood pressure, the less sure he becomes of any of the accepted interpretations regarding the test. His observations have led him to the following conclusions: (1) That systolic blood pressures indicate the presence in the circulating blood either of unexcreted putrefactive products absorbed from the intestine, from the kidneys, from focal infections in the dental alveoli, the nasal sinuses, the tonsils, the genitourinary tract, or of secretions in abnormal amounts from the glands of internal secretion. (2) That in some cases at least, a lowered systolic pressure indicates a defective secretion of pressor substances, or an increased secretion of depressor substances by the ductless glands. (3) That the diastolic pressure, when it fails to conform to its normal ratio with the systolic pressure, is also influenced by abnormal products of metabolism or by abnormal amounts of the ductless gland secretion in the blood stream. (4) He does not believe that either the systolic or the diastolic blood pressure gives any certain indication as to the condition of the cardiovascular renal system as such; but that when changes in the vascular system are accompanied by hypertension, neither condition is secondary to the other, both being secondary to the presence of unexcreted toxic products of metabolism in the circulating blood.

3. Some Remarks on the Psychology of Internment, Based on the Observation of Prisoners of War in Switzerland.—R. Bing and A. L. Vischer point out that any path of life which diverges from the ordinary and along which bodies of men find themselves obliged to travel will in a short space of time affect the mentality of the travelers, and that the same objective influences operating upon different minds often produce psychical results of striking similarity. This has been seen among the members of Arctic expeditions, among exiles in Siberian prisons, and particularly among prisoners of war in internment camps. The name of "barbed wire disease," or in French "psychose du fil de fer barbelé" and in German "Stacheldrahtkrankheit," has been given to this psychoneurosis. This name seems to have originated in Switzerland though its exact origin cannot be determined; it has, however, established itself so thoroughly that it is already found in international treaties. There are essentially three abnormal conditions reacting on prisoners of war: the deprivation of liberty, the heaping together of the prisoners one upon another, and the uncertainty of the duration of their internment. The monotony, and particularly the lack of privacy, engenders a nervous irritation which reacts with especial force upon the more sensitive personalities. At first the prisoners seek in a feverish activity an antidote to the remembrance of the horrors through which they have passed, the anxious waiting for letters and constant homesickness, and the anxiety for the future, but little by little interest in sports, theatricals, concerts, etc., disappears and they come to live in a grey and dreary shadowland; their emotions become blunted and give place to apathy. The first sign of a neurasthenia is an increase of irritability. The men will not suffer the slightest contradiction; they become argumentative and obstinate and exhibit a characteristic lack of judgment, and there is a great deal of quarreling. They lose the power of concentration, and pathological fatigue which makes it impossible to read even a few pages consecutively, has its counter part in the motor system and often leads the soldier to sacrifice the little exercise he is permitted. There is also a striking loss of memory of people and places. Among the secondary symptoms insomnia should be mentioned; in some camps it is widespread, in others unimportant. Asthenopia is particularly noticeable in artificial light. Many men grow suspicious, and all have a marked tendency towards pessimism. Sexual impotence is common. The authors have been interested in observing the effect of transfer to a neutral country on these nervous and physical anomalies. They have found that as a rule the unnatural irritability disappears within a few weeks of the arrival of the prisoners in Switzerland; on the other hand, improvement in intellectual stability and concentration takes place very slowly; there is, as the British say, "a difficulty in settling down." The men have the greatest difficulty in confining themselves to a single occupation or their thoughts to one order of ideas; very often they cannot even attend a cinematograph performance. Disturbances of memory are also very remarkable; one man was unable to remember the name of the village from which he came; another, a lawyer, could not remember about a trial in which he had been greatly interested, nor could he recollect the name of his client. This symptom is distinguished from other mental phenomena of the internment psychoneurosis by the fact that it is foreign to simple neurasthenia. Insomnia and impotence as a rule disappear, but many of the interned men give the im-

pression of a personality that has been profoundly changed. Their families, on coming to see them, find them completely altered; the authors, however, strongly insist upon the good influence that some of the men derive from the visits of relatives, as by this means a living contact is established with the family—the fundamental basis of social life. Among the intellectuals there is often an extreme sensitiveness; they tend, in spite of themselves, to misunderstand a gesture, a tone or even a silence. There is also a certain shyness, which is not misanthropy but a consciousness of abnormality. Many even believe that their nervousness has grown worse in Switzerland. This, however, is not the case and the authors assert that the nervousness, in reality, gradually decreases as a result of the changed environment. They add that these observations, though slight, will suffice to make manifest in a new light the great humanitarian value of neutral internment.

1. A Lecture on the Practical Importance of Vitamines.—F. Gowland Hopkins draws attention to the fact that in a proper diet sufficient for the needs of the body something more is required than the protein, carbohydrate, fat, and mineral salts which were formerly considered the only essential constituents. An efficient diet must possess vitamines, the importance of which is out of all proportion to the minute quantities in which they are consumed. That this is so is proved by the following: if animals are fed with a mixture containing pure protein such as purified casein from milk, purified starch, and pure sugar together with a vegetable fat and the requisite mineral salts, normal growth will fail in young animals and, sooner or later, all animals, even adults, will die. The author points out here that such a diet is wholesome, is fully digested, and can be eaten in ample quantity for growth and maintenance, and yet there is failure of growth and maintenance. If, however, a minute quantity of some preparation made from plant or animal tissues, for instance, milk which was used in the author's experiments, the young animals grew satisfactorily. The diet must contain something made originally by living cells. All our natural foods are parts of tissues which have lived and we owe our supply of them to the plant, for the plant makes and stores these essential substances in very small quantity. It would seem that these vitamines are not made in the animal body and that the animal depends ultimately upon the plant for a supply. They accumulate in the tissues of herbivorous animals and there, as well as in the plant, they are available for human consumption. Without these minute quantities of accessory substances, perfectly wholesome and necessary foodstuffs are not, in any complete and proper sense, utilized at all; they are absorbed and energy is liberated but the co-ordination of metabolism is absent. The exact nature of the vitamines is not known; but they are nutritive essentials not directly concerned with the supply of potential energy. Efforts have been made to effect their isolation, but as yet without success. There are at least three of these substances, each having its own function in nutrition. Two of these are of especial importance to nutrition; one associated with certain fats, the "Fat-soluble A," and one soluble in water, the "Water-soluble B." Both must be present in sufficient amount in any dietary providing proper nutrition. The prevalence of beriberi, a deficiency disease, in certain rice-eating communities of the East is a good example of this. The disease has been shown to be due to the use of polished rice, from which the vitamines containing "silver-skin," the thin layer which lies on the outer part of the husk-free seed, together with the germ or embryo has been removed by modern milling machinery recently introduced from the West. Reference was previously made to the effect of feeding an animal upon a non-vitamine containing diet, the fat given being a vegetable fat. If this vegetable fat is substituted by butter, or any other animal fat, growth will occur if small quantities of watery extracts made from various plant or animal tissues are added. Since the animal fat contains the "Fat-soluble A," all that is necessary is to add the "Water-soluble B," which is contained in the watery extract. If a vegetable fat is again substituted for the butter, the watery extract will naturally have no effect since the "Fat-soluble A" is lacking. Its absence from vegetable fats is due to the fact that it is left behind when the fats and oils are expressed and extracted. This substance is abundant in butter but, strange to say, absent in lard. The water-soluble vitamine is the substance which rice loses when it is polished, and is the very substance that is necessary for the prevention of beriberi. One of the special characteristics of this disease is a disturbance of the nutrition of the nerves; a degeneration of the nerves occurs with accompanying paralysis. Birds when fed exclusively on polished rice display this particular symptom; after three weeks upon a diet of polished rice, a pigeon or a fowl will suddenly develop acute symptoms of paralysis. The effect of absence of the fat-soluble vitamine in the diet is more difficult to observe, because animals possess a supply of this substance in their own fat stores and appear able to draw on this until their store is exhausted. It is probable that in rickets a deficiency of this fat-soluble vitamine plays a causative part. Mellanby has shown that dogs fed on a diet lacking this essential, though kept in healthy surroundings and given exercise, speedily develop this condition. He has also shown that this can easily be prevented by giving fats which are rich in the fat-soluble vitamine, though vegetable fats are without effect. The author states that although other factors, such as deficient hygiene, may be contributory, he is quite convinced that the dietetic error is the primary cause of the condition. Furthermore it has been demonstrated by Mrs. Edward Mellanby that deficient diets involve grave errors in the growth of teeth in young animals. Cod-liver oil stands preeminent as a fat rich in vitamines and capable of curing rickets in dogs, and it has long been known to have a favorable influence on the disease in infants. It has been found of great benefit in preventing rickets in infants in a negro community where the dietetic standards are low. Scurvy is another deficiency disease which arises when no fresh foods are available and which teaches us that a third vitamine exists, the antiscorbutic factor which, unlike the antineuritic ("Water-soluble B") or the fat-soluble substance is very unstable and is rapidly destroyed when fresh fruits are heated, dried or kept too long. Pellagra is also due to the absence of some specific necessary nutritional factor from the diet. To show the national importance of these facts, the author refers to the sufferings of the British troops from scurvy during the siege of Kut. He also points out that although the absence of certain factors, or their presence in insufficient quantities, in diet may not lead to symptoms sufficiently marked to be considered as a definite disease, malnutrition and a great deal of ill health may result which could be prevented. This is of course particularly true of the poor, whose food consists largely of bread. The elaborate milling and "refining" which the whole grain suffers before it appears in the form of our white flours deprives it entirely of its water-soluble vitamine, and this illustrates the danger of "fractionating" natural foods. Again, margarine is a vegetable fat and therefore is devoid of the fat-soluble vitamine. It is easily seen therefore that white bread and margarine is a desperately bad combination. Many of the advertised breakfast and invalid foods are also lacking in vitamines. In connection with the antiscorbutic vitamine, the author points out that tinned foods are largely used in poor households, chiefly because they require no cooking. He emphasizes the fact that absence of an essential vitamine means disease; but no more than a relative deficiency of a vitamine may mean bad nutrition. It is the children chiefly who suffer, and it is important that the facts should be recognized, as the consequent ill health is often misunderstood and wrongly treated. It should be recognized also that in the case of the nursing

mother, since vitamines are not made in the animal body, should her diet be deficient in vitamines her milk would also become deficient—to the complete detriment of the nutrition of the child. Professor Hopkins adds that the study of vitamines is yet in its infancy; he believes, however, that no matter whether these substances prove to be of more or less importance than is thought at the present time, the subject is one that should in any case awaken public interest.

1. The Physics of the Chest and Their Relation to Diseases and Injuries of the Thoracic Organs.—James Barr points out that in his Bradshaw lecture, delivered in 1907, he somewhat forestalled many of the observations on the chest wounds in the present war. Inter alia, he said: "With care atelectasis is easily differentiated from pleural effusion even when the dull percussion is absolute and the respiratory and vocal phenomena absent. In atelectasis of one lung the affected side is smaller than the other, the ribs are closer together and more sloping, the costal angle more acute, the diaphragm raised, the dull percussion barely reaches the middle line in front, while the sound lung passes beyond the medial line, the heart is either not displaced or slightly pushed over by the sound lung." In pleurisy there is no sudden arrest of the effusion as in hemothorax, but it gradually accumulates, and as the pressure becomes positive you get collapse from below upwards, but there can be no general collapse of the lung until the intrapleural tension becomes sufficiently positive to overcome the intrapulmonary pressure minus the elasticity of the lung. Even before there is any general positive pressure, if there be a difference in pressure in the two pleuras the heart may be pushed or drawn over to the side where the negative tension is the greatest. As the effusion increases the tension becomes more and more positive, and eventually there is not only complete collapse of the lung, but the heart and neighboring organs get much displaced, and the diaphragm pushed down so as to depress the abdominal organs. If you withdraw the effusion and substitute fluid air for the liquid you can now easily regulate the pressure, which then becomes equal all around the lung and not according to the depth of the liquid. If you are careful to leave a pressure in the pleura less than that of the atmosphere in the ultrapulmonary air sacs you encourage the gradual expansion of the lung and the restoration of its elasticity. On the contrary, in hemothorax the tension rarely, if ever, becomes positive, hence you get sinking in of the chest walls and a rise in the diaphragm which becomes fixed in its elevated position. Owing to the complete collapse of the lower lobe there is no intrapulmonary pressure to assist in the expansion of the collapsed lobe. In empyema the pressure is frequently higher than in serous effusion, and when the tension is very high there is not only complete collapse of the lung, but you may have the pulsations of the heart communicated to the liquid, giving rise to a pulsating empyema. The lung is kept expanded by the negative tension within the pleura, and the greater and more active the inspiration the greater the negative tension, but not infrequently, especially in many wasting diseases where the demand for oxygen is not great, the negative pressure may fall to a very low ebb or may disappear, especially at the base and posterior surfaces of one or both lungs, the inspiratory movements being confined to the upper part of the thorax. In such cases partial atelectasis is of one or both lungs, or almost complete atelectasis of the lung of the side on which the patient has mostly lain is not at all uncommon. Massive collapse mostly occurs in the lower lobes, and is especially apt to occur in young, flat-chested individuals with pliant chest walls. When these cases are discovered in the early stages they are frequently mistaken for pleural effusion, an error which is apt to remain uncorrected if an exploratory needle be not inserted into the chest. The careful physician should avoid exploratory operation until all other methods of diagnosis have failed him. With reference to emphysema, Barr says that in emphysema the chest becomes barrel-shaped, except in the senile type, and the costal cartilages rigid; so the chest walls assume their largest possible dimensions, the lungs lose their elasticity, the recoil of the chest walls and the intrapleura negative tension disappear. Consequently, the only part of the respiratory pump which remains in action is the diaphragm, which is a very poor affair compared with the movement of the pliant chest walls; thus the vital capacity is much diminished. If the pump action be completely abolished the blood can only enter the chest under positive pressure. The veins of the chest remain full and tense even in inspiration, and the right side of the heart does not receive any respiratory assistance. According to Barr if you wish to retain a healthy chest, you must maintain a good vital capacity, for which purpose pliant chest walls are essential. You must not allow any calcification of your costal cartilages to take place. In the respiratory pump action which maintains the vital capacity the movements of the chest walls are equivalent to more than double that of the diaphragm. Everyone should be taught chest breathing, and leave the diaphragm to look after itself: it is an adventitious agent which will naturally come into play when required. In emphysema the difficulty is not so much in getting air into the chest as in driving it out, hence a elastic band worn moderately tight around the chest assists expiration and gives more work on inspiration, which helps to establish a negative pressure within the chest. As for pneumonia, on the affected side the movements are diminished, the negative pressure is lessened and gradually becomes positive, but not to such an extent as to cause displacement of the heart and other organs. At first the loss of elasticity of the lung may be greater than that of the chest expansion, so that the intercostal spaces are depressed in inspiration. However, the affected lung may become so large as to abolish the recoil of the chest wall and the lung be marked by the pressure of the ribs. The blood is often badly oxygenated, but this is rarely, if ever, a cause of death, while on the other hand the greater percentage of carbonic acid in the blood stimulates the respiratory center and keeps up the pump action.

Le Progrès Médical.

March 29, 1919.

Syndrome of Raynaud.—Rathery reports seeing three cases of this syndrome in subjects attacked with chronic nephritis, tuberculosis, and diabetes. It is not strange that this experience should influence one to speak of syndrome rather than autonomous disease. The nephritis patient presented in a high degree the phenomena which characterize the syndrome. The entire history of the patient and even the family history showed marked predisposition to cardiovasculorenal disease for the mother had been a cardiorenal patient and patient had been attacked in her youth with both scarlatina and acute articular rheumatism. She had had one attack of hemiplegia from which recovery ensued. With the peripheral gangrene associated with the Raynaud syndrome were other areas of dry gangrene, as one in the region of one elbow which were doubtless due to arteritis of the same or an analogous type. Much more atypical was a case of gangrene in the feet seen in a diabetic. Such a condition is not usually classed under Raynaud's syndrome, but as a positive Wassermann was present the real motivation for the gangrene may have been a syphilitic arteritis. In addition tuberculosis was found at autopsy. The author appears to think that the presence of the chronic pulmonary trouble by disturbing the peripheral circulation (drumstick fingers, etc., were present) may have been a factor in the genesis of the gangrene. However, the fingers were not attacked by the gangrene, which was of the dry type in the feet and toes. Of the three factors present—diabetes, syphilis, and tuberculosis—no one seems to have the priority. The third patient suffered like the first from chronic nephritis, but without complications.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Thirteenth Annual Meeting, Held in Syracuse, May 6, 7, and 8, 1919.

(Special Report to the MEDICAL RECORD.)

SECTION ON MEDICINE.

(Continued from page 894.)

A Clinical and Bacteriological Study of Fusiform Bacillus Infection.—Dr. R. R. MELLON of Rochester made this presentation (by invitation). The speaker said he would confine himself to the clinical side of the picture. The word fusiform bacillus infection was used in the generic sense, indicating the organism responsible for Vincent's angina and ulcerative conditions of the throat. These organisms closely resembled the diphtheria bacilli, the streptothrices, and throat fungi. It had been difficult to infect experimental animals and the relationship to human disease had been questioned. Flexner, however, had produced lung lesions closely resembling tuberculosis, and Bunting had produced fibrosis in guinea pigs, by infection with diphtheroid bacilli. Actinomycotic lesions had been produced in the lungs which were very easily confused with tuberculosis. Case histories of this infection were cited. One, a young girl, 17 years of age, with chronic cough, relapsing fever, and occasional small hemorrhages. She was sent to Saranac Lake, but tubercle bacilli were never found and Dr. Kinghorn said the lesion was non-tuberculous. She had a purulent sputum which contained non-acid fast organisms of a fusiform type. The *x*-ray showed bronchiectasis with interstitial fibrosis. Subcutaneous injection of the organism in guinea pigs produced marked fibrosis. The second case was one of acute bilateral empyema which at the end developed mental symptoms and the patient developed extensive meningoencephalitis. At autopsy the lungs were negative. In the aortic valve were millions of coccoid and bacilloid forms. The cerebrospinal fluid was purulent. Case three was a unilateral empyema. Case four was an acute bronchitis. Case five a gangrenous balanitis. The man went five months without consulting a physician and when seen the penis was the size of an orange. There was a purulent exudate with millions of fusiform organisms. Wavy filamentous forms were isolated from the blood. The Wassermann test and complement fixation for gonococcus were negative. The sixth case was gangrene of the lower extremities, diagnosed as Raynaud's disease. There was history of severe mouth infection. The Wassermann test was negative. The seventh case was one of painless arthritis of the knee in a boy. The exudate showed myriads of coccoid organisms and filamentous forms. After tonsillectomy the patient recovered. The eighth case was one of Dupuytren's contraction following streptococcic infection. There was slowly progressing adenitis with spondylitis. A pure culture of a spirillum was obtained from the tonsillar crypts. With tonsillectomy there was disappearance of the spinal symptoms, but no effect on the Dupuytren's contraction. There was one case of mandibular ulcer; one of dropping out of the teeth in a boy six years old; two cases of mycotic pharyngitis; one of mastoiditis; several cases of post-partum fever; one case of toxic hypochromic anemia simulating pernicious anemia; one unilateral salpingitis in a very young child in whom there was obviously no gonorrheal infection. In all of these cases the same coccoid form was found frequently associated with wavy, filamentous forms in the blood. Some of these forms might be secondary invaders, but in view of the pathology one was not justified in regarding these organisms as purely saprophytic.

Dr. AUGUSTUS WADSWORTH of Albany said it was of the utmost importance to have records and cultures of infections that simulated tuberculosis. It was interesting that Dr. Mellon had been able to gather so many cases apparently incited by this organism. The inference might be, although this was not certain, that there were a much larger number of cases living. In many cases of supposed tuberculosis it was difficult to demonstrate the tubercle bacillus and one was at a loss to know what to do. To order the patient to a tuberculosis sanatorium was to run the risk of infecting by contact a non-tuberculous patient. Therefore these studies were of the greatest importance and Dr. Mellon was to be congratulated upon the care and thoroughness of the pathological and bacteriological studies of his cases.

Dr. MITCHELL of Albany said that this fusiform organism associated with a spirillum was very commonly met with. It caused a necrotic condition of the tissue with foul odor, described by Dr. Mellon. Just what the relationship was of the organism to the condition was not yet clear. It was constantly met with in wounds and the laboratory worker could describe the wound to the surgeon by observing the flora found there. There was marked necrosis of the floor of the wound. In regard to the mouth, conclusions should be drawn with the greatest care, as these were the predominating bacteria found there. Many mistakes were made by calling ulcers round the gums Vincent's angina. Everybody's mouth would yield such organisms. Dr. Mellon's work was very instructive, but he thought that Dr. Mellon did not want them to conclude that the flora was the cause of the necrotic lesion.

Dr. JENKINS of Albany said he was not a laboratory man, but he had worked at Plattsburg and when in doubt he referred things to Dr. Wadsworth. There were two cases of doubtful diagnosis: one supposed to be tuberculosis had a leucocytosis of 25,000. There were no tubercle bacilli, but there were fusiform organisms. At Camp Choate there was one case reported diphtheria, but the findings showed a pneumococcus. Another was a case of marked gingivitis in which the smears showed fusiform bacilli and spirilla. One case had a plus Wassermann and the medical officer mantained that the cases were syphilis. The dentists got many cases. With the use of formaldehyde they recovered promptly.

Dr. MELLON said that he had not been able to present conclusive evidence that the organism found was the cause of the condition. Experimental work on animals was still being carried on. As to the fact that the fusiform bacilli were found in the pharynx and mouth, he did not think that had any weight, because the same thing was true of the streptococci, especially *S. viridans* and sometimes *S. hæmolyticus*, in which case there was no pathological lesion. The same thing was true of the intestinal tract. These infections were conditional infections—in fact, all infections were—and some were more virulent than others, but, as Dr. Cole and others brought out the day before, although the pneumococcus was the organism that caused pneumonia, there were a large number of other factors of a preliminary nature which made it possible for the pneumococcus to take root, and the same thing was true to a greater degree in this infection. A large number of the cases of "trench mouth" reported in England seemed to be contact infections. There was no proof that the organisms found in normal mouths could not become pathological under certain conditions.

The afternoon session was a joint meeting with the Section on Surgery, and was devoted to a Symposium on Anemias.

DR. A W. BOOTH OF ELMIRA IN THE CHAIR.

Diagnostic Methods.—Dr. ARTHUR HAWLEY SANFORD of Rochester, Minn., made this presentation (by invitation). The subject, he said, was so large that it was impossible to do justice to it in an afternoon's discussion. Some of the points which he was obliged to leave out, he hoped would be touched upon by other speakers. The Addison type of pernicious anemia had been termed by some writers the "so-called" pernicious anemia. There was some unknown cause operating which accelerated blood destruction. The true, primary pernicious anemia was very difficult to differentiate from other diseases which have anemia for a cardinal symptom, but perhaps owing to better ob-

servations, the profession were certainly diagnosing more cases of pernicious anemia than they did ten or fifteen years ago. In patients with a color index of one, with a slight icteric tinge of the skin, and with complaint of general weakness, one might suspect the disease. Certain diagnostic points had been evolved to aid in determining the conditions, such as the analysis of gastric contents, consideration of neurological symptoms, fragility of the erythrocytes, presence of urobilin or urobilinogen in the stools or urine, presence of syphilis, examination of the stools for parasites, inspection of the mouth, especially the tongue, teeth, and tonsils. In pernicious anemia there was usually found an achlorhydria with absence of free acids. The nervous symptoms of pernicious anemia resembled those of tabes dorsalis, but the involvement was not only in the posterior columns, but in the anterior horns as well, and definite degenerative areas in the posterior portions of the cerebrum were noted. The clinical manifestations of somnolence and delirium, however, were probably of toxic origin. Reactions showed that the sensations of heat and cold, pain and touch, were diminished, but reflexes were increased rather than diminished, as in tabes. The Babinsky reflex was increased, and there was Romberg sign with spasticity, rather than ataxia of gait. Of 150 cases examined at the Mayo clinic, 80 per cent. showed nervous tissue degeneration. Ophthalmological examination also showed changes in the retina. As regards other anemias with somewhat similar symptoms, the anemias of ancylostoma and that associated with *Bothryocephalus latus* had been described by some writers as "pernicious anemias with known etiology." Hemolytic jaundice presented a similar blood picture to that of pernicious anemia, but a differential diagnosis was of importance because splenectomy often originated a cure in hemolytic jaundice. Schneider's test for hemolytic jaundice consisted in the recovery of urobilin and urobilinogen from the duodenal contents by the Einhorn method. In this disease the bile registered 3,000 to 4,000 units, as against a normal of a hundred units. In severe anemias a Wassermann test should be made to exclude syphilitic anemias. Many patients responded to antisyphilitic treatment, but some did not do so until after the blood picture had been improved. Some patients whose blood gave a positive Wassermann did not respond to any therapeutic measure, and the question might arise "Does the pernicious anemia produce changes in the blood which give rise to the positive Wassermann reaction," The evidence was doubtful, because many cases of pernicious anemia did not give a positive Wassermann. In anemias due to parasites, such as hookworm and *Bothryocephalus latus*, proper treatment brought about a cure, but often in pernicious anemia there was an amebiasis, which, however, was probably due to secondary infection caused by lowered resistance. The removal of the parasite did not change the blood picture. *Balantidium coli*, a tropical parasite, frequently caused the blood picture of pernicious anemia. Inspection of the mouth in pernicious anemia was important and would reveal the absence of the papillæ—the typical "ball tongue"—with more or less severe glossitis. The splenic anemias and the pseudoleucemia (of von Jaksch) were not easily confused with pernicious anemia. They were curable by surgery, and the anemia due to myxedema could be modified by endocrinal therapy.

Medical Treatment.—Dr. Louis Virgil Hamman of Johns Hopkins Hospital, Baltimore, Md., read this paper (by invitation). He said that ignorance prevailed as to the etiology and pathology of the disease. The clinical features were not peculiar to pernicious anemia and consequently the diagnosis had to be one of exclusion, and sometimes the disease was only discovered at autopsy. There were many clinical manifestations of the disease, but one was still ignorant of the way in which the anemia was produced, and the term "hemolytic anemia" did not explain the reactions which occurred in the bone-marrow structure or the state of its exhaustion of production. Under such conditions one could not expect much from treatment, and, strictly speaking, there was no treatment beyond palliative measures. The disease was never cured, but carried the patient down to death. The question arose, however, How far can this termination be postponed? Data were necessary concerning the course of the disease, and yet this had not a smooth and regular march; it progressed with frequent pauses and remission, causing the therapeutist to ignore this tendency and suppose that he had restored the patient to health, happiness, and useful occupation. These states, however, were at best but fleeting. The onset of the disease was insidious and difficult to determine as to time; some patients died within six months, others lasted ten years or more. In regard to treatment three points could be borne in mind: (1) The choice of method to employ; (2) the search for indications as to whether the disease was advancing or was getting better; (3) reliance could be placed on impression gained by daily contact with the disease. Aids to therapy were many and included attention to hygienic diet, with perhaps forced feeding; baths, massage, administration of hydrochloric acid to aid digestion, arsenic, removal of foci of infection, transfusion, and sometimes splenectomy. The reactions to transfusion varied in different patients. In some there was a steady rise of hemoglobin; in others only a transient rise, followed by a fall to the original level. Some patients could be kept alive by repeated transfusions, some grew worse in spite of them. From an analysis of cases at the Johns Hopkins Hospital it was found that neither transfusion, splenectomy, nor removal of foci of infection produced any more lasting or any better results than the older methods of treatment. In one patient, a man who had no other treatment than rest in bed, the hemoglobin rose from 22 to 78 per cent. and the red blood cells from one million to three and one-half million. The blood picture showed so many exceptions and variations in various cases that it could not be used as a gauge to value the methods of treatment. Results therefore had to be estimated by clinical impressions, a very loose standard, but one which allowed the clinician the widest latitude. The speaker said he could sum up his impressions as follows: Recent methods had not altered the results in pernicious anemia. *When* treatment was given was more important than *what* treatment was given; sometimes all methods would cause improvements, sometimes all would fail. Perhaps more desperately ill patients had recovered with the help of transfusion than without it. Remissions were often hastened and sometimes inaugurated by it. Splenectomy had a high death rate and was a formidable procedure, and for this reason had been abandoned at Johns Hopkins. Pernicious anemia was inevitably fatal and treatment could but permit and prolong the remissions. Success, it would seem, depended more upon the use of all methods and the proper combination of them, rather than upon one alone.

Surgical Treatment.—Dr. Donald Church Balfour of Rochester, Minn., sent this presentation, which, in the author's absence was read by Dr. Hunt of Rochester, Minn. Surgery, it was stated, bore an important relation to the treatment of the anemias of splenic origin. It occupied a minor place in the diagnosis and differentiation of the condition, but once the diagnosis was made the surgeon's work was begun. Indications for splenectomy were hemolytic jaundice, syphilitic splenomegaly, Gaucher's disease, and gastrointestinal hemorrhage. In syphilitic splenomegaly operation could restore the blood picture and procure a negative Wassermann. In gastrointestinal hemorrhages, occurring sometimes without a lesion and from results of toxemia, splenectomy caused cessation of the hemorrhages. In pernicious anemia splenectomy was of no avail. In myelogenous leucemia the size of the splen was a direct indication of the severity of the lesion. Its reduction could be effected by radium and after that removal of the spleen could be undertaken, but it was doubtful if the result would be permanent. The operation of splenectomy, as a rule, could be carried out without difficulty and without higher mortality (2 per cent.) than that of other abdominal operations. Sometimes, however, the operation was very difficult. The procedure consisted in an incision close to the left rectus, carried up high to the sternal notch; the gall bladder and liver were thoroughly explored. The spleen would be found in anatomical contact with the diaphragm, the left kidney, the colon, and the pancreas. The spleen was freed from adhesions to the gastrosplenic omentum, and a large pack was placed where the spleen was to be re-

moved to prevent oozing. After ligating the vessels of the pedicle the organ was removed. No unusual risk was run by the operation and it was specific in anemias associated with enlargement of the organ in question.

Transfusion Method.—Dr. RICHARD LEWISOHN of New York presented this paper. He said that his experience with other methods than the citrate was a limited one. In the method outlined the usual attention was paid to the proper grouping of the blood, and the classifying of the blood of the donor and of the recipient in the same group. With care as to transfusion in proper quantity there was then no risk either to donor or to recipient. The methods of vessel anastomosis required skillful surgery, therefore transfusion was not resorted to as often as the welfare of the patient required. Lindemann and Kempton and Brown had done work toward the simplifying of blood transfusion, but the citrate method was fundamentally different from the others in that it made use of a chemical to prevent coagulation of the blood, a result never entirely successfully obtained by other methods. The sodium citrate employed was a nontoxic substance and would prevent coagulation for twenty-four hours. Two steps were necessary: (1) taking the blood from the donor; (2) injection of the citrate into the recipient. Very simple apparatus was needed—a large graduated glass holding 500 c.c., two small flasks, a salvarsan flask, and two cannulas. The insertion into the vein of the donor presented the only difficulty. The donor should be a robust man and a professional donor was to be preferred. Sometimes as much as 900 to 1,200 c.c. was taken. The donor was removed before the recipient was brought in and the second stage was the intravenous infusion of the patient. It could be said that the citrate method did not appeal to all members of the profession on account of the introduction of the chemical into the blood. The coagulation time was a little shortened thereby, but returned to normal in twenty-four hours. More chills were observed by the citrate method—that is, 20 per cent., as compared with 10 per cent. The method was of use in four groups of cases: hemorrhage, pernicious anemia, preoperative and postoperative transfusions, and sepsis. Its harmlessness was proven by the lack of toxic effects in infants. In cases of severe hemorrhage it was well to have a donor ready so that no time should be lost. This method could be used with advantage in the rupture of ectopic pregnancy. The experience gained in the war had proven the advantages of the citrate method. Preoperative transfusion often helped the patient to withstand the shock of the operation and postoperative transfusion assisted him to overcome the effects. In pernicious anemia the results were not permanent, but it did give a temporary rise in hemoglobin; in leucemia it was of no value. Work in the future could be directed toward immunizing donors, so that the blood could be ready in acute cases and in extreme sepsis. The question as to whether the blood of the donor actually lived in the body of the recipient had been studied in a very interesting way by Miss Ashly of the Mayo clinic, and it had been found that the blood did actually live in the recipient's vessels for about thirty days.

Dr. EMANUEL LIBMAN of New York said that he would like to take up one or two interesting points that had been made. Dr. Sanford had described very fully the newer method of diagnosis of pernicious anemia. One of the most important older diagnostic methods was the presence of macrocytic blood, with a color index of one or over one. It was important to look over the blood very carefully and, by the presence of macrocytes one might diagnose the disease long before the patient became anemic. The nervous symptoms also were important for diagnosis. In pernicious anemia there would often be found a Babinski reflex on one side or on both, and no other form of anemia, so far as the speaker knew, would give the Babinski reaction. The question of differential diagnosis between pernicious anemia and neoplasm would have to be considered. In new growth there was a similar blood reaction, but the index was usually below one, and there would sometimes be found cells in the blood which were characteristic of new growth. In regard to aplastic anemia, this term could be applied where there were no nucleated red blood cells and no erythroblastic cells in the bone marrow: the lymphocytosis was very high. Aplastic anemia was rare and some of the cases so termed were really cases of aleucemic leucanemia. The importance of recognizing these last cases lay in the fact that there was no result to be obtained by transfusion or splenectomy. The speaker said that he agreed in the main with Dr. Hamman, but he did not consider that focal infections had any influence in the causation of pernicious anemia. As soon as one found the cause of an anemia, it was no longer a case of (so called) pernicious anemia. It would be well to attend to minor infections of the teeth and so on, but such important procedure as surgery of the gall bladder had better be left alone, except in cases of emergency. Arsenic, of course, might be of use on account of the tonic effect. In regard to the treatment of the intestinal tract, usually there was increased putrefaction in the tract because of the lack of normal *B. coli*. The artificial implantation of *B. coli* in some people had aided in lessening the autointoxication and had raised the efficiency of the patient, and in this sense the method would help along. As regards transfusion, it was important to consider the hydremic cases. They should be put first on the Carrel diet or else one might get cardiac insufficiency or congestion of the lungs. It could be said that transfusion did not cure pernicious anemia, but it did surely help. Dr. Libman said he had been watching pernicious anemia for twenty years. Transfusion had given some benefit. It might initiate a remission. The patient felt an immediate result and the use of transfusion certainly put him into better shape for the time he had to live. It raised the blood figure and improved the difficulties due to anemia, removed mental symptoms, caused the patient to eat and digest better, although it never brought back the hydrochloric acid or stopped the glossitis. Often the patient would declare that his tongue was better, although really this was not changed, nor was there a real difference in the neurological condition. Cardiac efficiency was certainly raised and systolic murmurs would tend to disappear when the hemoglobin was raised (in general at about 60 per cent.). In pernicious anemia one had a reduction of the functional capacity of the kidney and this could be raised by transfusion. To use the term pernicious anemia was to call the disease by only one of its symptoms. The anemia due to an unknown toxin, the glossitis, the achylia, and the nervous symptoms were all part of the general process of which the anemia was but one manifestation. In the giving of transfusion, one point was of great importance and that was not only to make a Wassermann test of the donor, but also to examine the man from head to foot. In one case of which the speaker had heard a man who had a chancre concealed the fact from the physician. His Wassermann was naturally negative and he was used as a donor, with the result that syphilis was communicated to the recipient. In another case with a negative Wassermann the donor had gumma of the liver. Another point was that if the same donor was used again and again, tests should be made for agglutinins and hemolysins, because it appeared that isolysins could develop in the blood of the recipient. In regard to the citrate method, Dr. Libman said his cases of anemia had been mainly transfused by the Unger method; the earlier cases by the suture methods. The citrate method would probably have given the same results. Two points were to be noted about the citrate method: chills were more frequent in febrile patients; in cases without fever the figures for chills were higher with the citrate method than with the direct methods. Therefore, in cases in which the patient suffered from a long standing chronic disease and was in a critical condition, it was better to use the non-citrate method. A sharp chill might put the patient in peril of his life. Another question was whether there were any difficulties in cases of renal disease. In one case seen the patient suffered suppression of urine for 24 hours after a citrate transfusion. It is true that he might have had block of the kidney from the ordinary method, but the introduction of a renal stimulant like citrate might exhaust a depressed kidney. This question should be studied for both types of transfusion. In cases of pernicious anemia with fever (over 60 per cent. had fever) the effect of transfusion was to lower the temperature to nor-

mal and there was no return of fever until the hemoglobin went down again. Splenectomy was apt to initiate remissions just as transfusion was. It did more, because it decreased the hemolysis, and as Schneider's studies had shown, stimulated the bone marrow and decreased the fragility of the red blood cells. Splenectomy carried with it a certain amount of risk, although at the Mayo clinic they had had one series of 29 splenectomies in pernicious anemia without one death. Some cases, however, developed thrombosis. From the reported cases it appeared that splenectomy was of most value in certain cases, namely, those in younger individuals, with large liver and spleen and marked hemolysis. Dr. Libman said that his plan was as follows: If the patient was suffering from anemia of the disease, a transfusion was performed. If that did no good, a second was tried. A remission was obtained, and transfusion was performed when the hemoglobin definitely began to drop again. Transfusions were performed as long as remissions of about three months or over were obtained. After that splenectomy was advised in properly selected cases, and after a remission, due to the latter, terminated, transfusions were again performed. It was important to determine whether a patient holds transfused blood better than before removal of the spleen. The present opinions were in conflict. Dr. Libman described briefly a case which was under treatment for seven years, having had eighteen transfusions done and also a splenectomy. This case and others made it clear that, whether or not one decided that transfusions and splenectomy prolong life, the patient was put in much better condition for a larger part of the duration of his life.

Dr. H. L. Brown of Rochester, N. Y., said he would like to ask Dr. Sanford and Dr. Hamman if they had run across any very early cases in the medical draft. In one young man of 22 years of age he had met with a count of two million red cells and hemoglobin of 40 per cent. The man said he had followed the plow and did not complain of any discomfort. Another point was the autointoxicaton. The giving of *B. bulgaricus* had been known to improve the patient in a surprising way. It was correct that the intestinal tract had something to do with the disease.

Dr. Sweet of Syracuse said that there was no doubt that the citrate method of transfusion was the best for practicability and simplicity. It had its restrictions, but used as in the A. E. F., and confined to cases of shock and hemorrhages, it answered exceedingly well. In his own practice the method was used (with some hesitation) in two cases of typhoid hemorrhages. One patient died with severe toxemia, the other recovered. In the A. E. F. a slight modification was introduced, large needles being used instead of cannulas. He personally had never cut down to the vein of the donor, but this was sometimes necessary in dealing with the collapsed vein of the recipient. They used a two bore rubber stopper on the container and the blood flowed by gravity into the bottle, which already contained the citrate solution dissolved in physiological saline. Before introducing the blood into the recipient's vein another sterile stopper was inserted into the bottle, which was placed in a can of warm water to keep the blood warm without subjecting it to atmospheric conditions. The procedure was so simple as to be a medical operation rather than a surgical one, if the details were carefully followed. It was necessary to have the needles sharpened every time before using.

Dr. Bowen of Buffalo, N. Y., said that one of the important things in pernicious anemia was the rate of the hemolysis and there was no good way of estimating this accurately; one had to go by qualitative tests, as, for instance, urobilin and urobilinogen. Those cases with a great deal of hemolysis were benefited by transfusion. The achylia cases received benefit from splenectomy. One patient had been coming in at intervals for two years for transfusion, from which beneficial results were obtained for a time. She had no icterus nor had she the urine and stools of pernicious anemia. Another patient whose diagnosis was aplastic anemia, was transfused with 1100 c.c. from his brother, and the blood came up a little. The next time it was without result. The family thought that an outside donor might be better and 500 c.c. was transfused from an homologous donor. The patient rapidly developed severe chills and died in coma. It was thought that this was anaphylactic shock, but the urine did not show hemoglobin nor did the blood show agglutinins. The tests for donor and recipient showed the types were homologous. The only possible explanation was that the patient was sensitized to sodium citrate and since then it had been the custom first to inject 30 c.c. with citrate and wait 15 minutes before completing the transfusion.

Dr. D. Olin of Watertown, N. Y., said that with the use of the sphygmomanometer cup one could get the maximal flow of blood.

Dr. Sanford, in conclusion, said that he had often heard the heresy expressed that it was not necessary to select the donor, and that some man had done 150 transfusions without any test at all and no ill result. He believed that by neglecting the group tests one ran a great risk. One had to be sure that the recipient's serum did not agglutinate the donor's corpuscles. A good and tried method was to take the recipient's serum with a corpuscle suspension from the donor and watch for a few minutes for agglutination. The agglutination reactions covered the hemolysins, as had often been brought out. Dr. Lewisohn's method was more than intravenous medication; it had been described as tissue transplant and required a great deal of skill and judgment to accomplish. One word could be said about Miss Ashley's entirely original work which merited attention. She took a recipient of a different group from the donor. All of the recipient's corpuscles were agglutinated with a large quantity of type four serum. The recipient's serum did not agglutinate type four corpuscles. After the transfusion she took the recipient's blood mixed with group four serum and then a large quantity of agglutinated corpuscles, then the transfused group four corpuscles and made daily observations until the agglutinated corpuscles disappeared from the recipient's blood. From these studies she concluded that the donor's corpuscles lived in the recipient's serum thirty days.

Dr. Hamman, in conclusion, said that Dr. Libman misunderstood him in thinking that he said that foci of infection played an important part in pernicious anemia. Sometimes, however, the removal of these did improve the patient's general condition. In one case where the patient had remained stationary for one and a half years an attack of gallstone colic made operation necessary. The patient improved very much after operation, perhaps on account of the cessation of digestive disturbances. Dr. Bowen had mentioned the early stages; the profession should be on the lookout for this incipient period when nervous disturbances could be looked for, also the papillary atrophy of the tongue. A careful examination would also reveal macrocytes in the blood.

Dr. Hunt of Rochester, Minn., said that he could not add much to Dr. Balfour's paper. He could speak for the success of the Lewisohn method of transfusion. In the Mayo clinic they had used it 1,400 times with practically no alteration of technique. They transfixed the vein with a little cambric needle, described by Watson in the *Journal of the A. M. A.* They did not cut down to the donor's vein and in less than 5 per cent. of cases of the recipient's. The importance of group tests could not be overestimated. In one case at the Mayo clinic, through a clerical error in tabulation the wrong donor was chosen, and the reaction was fatal. It was not interpreted rightly, as the error was not known. Now, however, they had learned to interpret pain in the chest and in the lumbar spine as danger signals. In one case with the wrong donor the patient recovered, but only after a stormy convalescence with evidences of hemoglobinuria.

Dr. Lewisohn, in conclusion, said that he had never seen a chill following a severe hemorrhage, and he had never seen a chill in an infant. As far as modifications in technique were concerned, he felt that it was useless to recomplicate a method that had been purposely simplified. In regard to the group tests, these made the popularization of the method impossible, because it was difficult for a man in a small place to have the proper laboratory facilities. Personally

he had never had a disaster himself, because he always left the testing to a laboratory expert. The practitioner was apt to make mistakes and this might cost the patient's life. He was at a loss to explain the accident to Dr. Bowen's patient.

Third Day—Thursday, May 8.

DR. A. W. BOOTH OF ELMIRA, N. Y., IN THE CHAIR.

Camp Work in the United States; Organization, Foot Inspection, Shoe Fitting, Moving Pictures.—Major WILLIAM C. PETERS and Major R. T. TAYLOR presented this subject, which was read by Major Taylor of New York. The speaker said that it had early become clear that oral instruction must be supplemented by illustration, in order to cover the vast educational field that the Government planned. Film instruction was found to be of far greater value than lantern slides, because it was easily transportable. It was used for medical officers, for line officers in order to teach them to look out for the disabilities that would produce stragglers, and for the men themselves to show them how to avoid defects. The illustration laboratory took care of three points of instruction: (1) lectures to prepare men for overseas duty, (2) films illustrating proper splinting of wounds, (3) reconstruction methods after wounds by arthroplasty, plastic operations of the soft parts, and bone grafting. A standard war manual was used which covered the disabilities of the foot and leg and dealt with the anatomy and physiology of locomotion. Flat foot was called "acute foot strain," because it was found that many cases with perfect arches suffered acute foot strain, while many others with congenitally flat feet (notably the negroes) suffered no symptoms of foot strain at all. The majority of men had to be taught how to stand and to walk in order to prevent foot strain. The men taken suddenly from sedentary desk work could not undertake the long hike with a pack of 50 pounds weight. These men were apt to walk with the foot averted, so that the strain was thrown entirely on the arch. The acute strain had a sudden onset in these cases. The men had to be shown how to walk and stand "pigeon-toed" in order to counteract the disability. Marked persistent swelling of the legs and feet, however, was found to be of infectious origin. The treatment was by enforced rest in bed, massage, and passive movements, contrast baths (50° and 110°). The foot was strapped in adduction, with the supports following the direction of the tibialis anticus muscle and carried well up the leg. The patient was permitted to walk gradually, after the heel on the inside of the boot had been raised. Exercise was necessary for weak muscles of the foot and leg, instead of the usual practice of raising the arch by metal appliance. If one considered the analogy of the muscles of the foot and hand, it would be seen that unexercised muscles tended to become weaker. A pianist, for instance, exercised the muscles of the hand to get more power. One exercise which was very popular with the men was a rotating movement of the thigh and patella which, as a consequence, pulled up the arch of the foot. In ankle strain the foot was strapped in pronation to approximate the torn ends of the ligaments as nearly as possible and to facilitate repair.

Medical Organization Overseas.—Lt. Col. ROBERT B. OSGOOD of Boston made this presentation. He said that the first combat unit sent overseas was a medical unit. The British Government had sent for medical units and the preliminary preparations had been made in such good order that the first unit was ready to leave within ten days. An urgent need was for workers to man and organize special hospitals. The cases of bone and joint disabilities were flooding the general hospitals and bone and joint men were greatly needed from America. Twenty men were sent over under Col. J. Goldthwaite in June, 1917, and later ninety bone and joint men went over to get their training in England although at that time troops were going over in small numbers. Preliminary American work was carried out in French and British hospitals. In France the difficulties of organization were very great. Hotels and monasteries had to be equipped as hospitals, and the first consideration in this work was to try and avoid the large number of preventable deformities, such as ankylosed joint, that might ensue. Perhaps 50 or 60 per cent. of the deformities were preventable, and often were harder to correct than the wound itself. Proper splinting of the limb was perhaps the most important factor in this respect. It was found that the British were using fifty kinds of splints and the French perhaps three hundred, and it was manifestly impossible to teach an intelligent handling of so great a variety. Finally the American organization limited the number to seven of the most practical and useful splints, which covered the ground satisfactorily. The credit of this work belonged to Major Allison, who got wonderful results through the simplification of methods. The regimental surgeons and stretcher bearers were trained in practical methods of splinting, and the methods carried out in the evacuation hospitals saved a great deal of time and added much to the comfort and prevention of disability in the wounded. Genitourinary men and psychiatrists, for the examination of shell-shock, were also attached to the evacuation hospitals. With the application of practical splinting, large numbers of wounded could be transferred long distances without danger or discomfort. The open wire type splints were used, which involved traction as well as fixation. Later the cases could be grouped in special hospitals, where a certain amount of reconstruction work could be done. Finally, the men went to hospitals on the coast which were used as clearing houses. In transporting men overseas the naval surgeons were apt to think that the splints could be discarded, but it was found that this resulted in many deformities and the practice was stopped. At the debarkation hospital the question was studied as to whether the methods had accomplished results. Not more than 5 per cent. of bone and joint deformities which could have been avoided were noted. The deformities that occurred were because the men here were not as fully trained in the conservation of function as they were over there. The untrained men were in the position of the negro soldier who complained that he was kept in the dark as to the direction of the troop ship. He was asked by the officer what good it would do him to know. He replied, "Becos, suh, ef de ship sink, how 'mah gwine to know de weh to swim fo' de sho'?" It was a big question to know in which direction to go. One word should be said as to the cooperation of the regular army officers with the medical men. They had had a rather green lot to deal with and they had helped them in a very kindly fashion in regard to army regulations, and in professional questions the medical men had always had the final voice. The general staff had a medical representative to whom questions were submitted and the spirit of the regular army in these matters deserved great credit.

Surgery of the Front and Evacuation Hospitals.—Col. CHARLES H. PECK of New York presented this communication. He said that the work of the evacuation hospital behind the battle front was different from that of the regular army organizations. It consisted of emergency surgery, treatment of shock, rest and recuperation before the journey to the base hospital, which was sometimes hours or days behind the fighting line. All the war wounds that went to the base hospital were suppurating wounds; the loss of life was great and the loss of function excessive. Early operation—that is, within twelve or fifteen hours—was of great importance in saving function. With the Carrel-Dakin technique a delayed method of primary suture was possible, and DePage, LeMaitre, and Duval had been able to carry out wonderful work by this method. In the work near the front line the work had been organized by surgical teams who worked day and night with a trained personnel. Cases could be operated on within a few hours and projectiles could be located by radiograph. With the shifting battle line of 1918 the organization had to be changed to mobile units who could maintain a relative distance from the front line. The trifling wound cases, which were of the highest importance from the military standpoint, could be treated and the men made fit to return to the battle front within a short time. This fact was recognized more and more, and hundreds of these cases were cared for almost immediately. In another type of wounds, those of the soft parts (excluding fractures), most brilliant surgical results were seen. Knowledge of anatomy, clean technique, and removal of all devitalized tissue were of the utmost importance. In these wounds a delayed primary suture was of great

advantage. The avoidance of gas gangrene, caused by too early suture, was learned by this method. The dictum was made that no wound should be closed early unless the operating surgeon could watch the case himself. The practice was established to pack the wound with gauze, and the bacterial count was watched in order to determine when safe closure could be made. Wounds characterized by anatomical loss were not suitable for primary suture, and these were best kept open and treated by the Carrel-Dakin technique. A proper treatment of fractures at the evacuation hospital avoided many deformities. In times of great stress, with a movable battle line and constant mobilization of the hospital, this was not possible. Under these conditions the orthopedic men did wonders in preventing deformities by applying proper methods of splinting and thus preventing deformities and osteomyelitis. At the evacuation hospital the treatment of the wound was the first issue, and this was done by the general surgeon. At the base hospital further mechanical treatment was given. The general tendency was toward conservation of fragments whenever possible. In joint wounds the wound was closed (but not too tightly) and active motion was commenced at once; this helped to pump the fluids out of the joint and was found to be a great advance in treatment as it prevented atrophy of the joints and muscles. Closure without drainage was the routine, and the successful treatment of joint wounds was a brilliant chapter of war-wound history. Much brilliant work had also been done on wounds of the thorax and of the head, and the work of Cushing in this field was noteworthy.

Surgery of the Peripheral Nerves.—Major CHARLES HARRISON FRAZIER of Philadelphia read this paper. This type of surgery, the speaker said, did not commence until the soldier went to the general hospital. There were twelve hospitals where lesions of the peripheral nerves were treated, and at which there were consulting neurologists and practitioners of nerve surgery. The surgeons on peripheral nerve lesions were asked to prepare a report for the Surgeon-General, to give an idea as to the end results. About 3,000 cases of these injuries had been treated and there were still some 411 waiting to be transported. One hundred and thirty-seven cases had recovered spontaneously, and there were still 125 to be operated upon. The decision for or against operation was based upon the proper interpretation of findings; the nicest judgment was required and experience gained from the study of war wounds was a prerequisite. There was a question of how long one should wait before operating, and it had been the rule to wait for three months after the wound had healed and thus to avoid chances of nerve infection. The appearance of false movements had to be disregarded, as, for instance, in complete ulnar paralysis another set of muscles might contract and lead the surgeon to believe that spontaneous recovery was about to take place. Thus if the flexor tendons were shortened, to extend the wrist would draw the fingers up. In operating, the differentiation between transient block and complete physiological division should be made. A free incision was necessary so as to expose the nerve well, otherwise there was great difficulty in recognizing one structure from another in the mass of scar tissue. In about 34 per cent. of the cases complete anatomical division had been found; 25 per cent. of neuromata; lateral neuromata, 2 per cent.; neuritis, 1 per cent.; pressure by bands and adhesions, 14 per cent.; aneurysm, 1 per cent. A preliminary dissection and disentangling of the nerve was necessary, and in 30 to 50 per cent. of cases a liberation of the nerve from scar tissue. This was better than suture as the nerve responded more promptly to faradic stimulation. With a sclerotic nerve there was no faradic response and one had to do resection. Neuromata, *per se*, did not impair the growth of the nerve; examination showed the formation of neuraxes or axis-cylinder processes, and the patient might have spontaneous recovery. In performing a neural operation, it was necessary to find a bit as free from scar tissue as possible, and sometimes one had to move the nerve to a more superficial plane, laying it in a bed of fat. It was not advisable to lay the nerve in a muscle bed as the scar tissue might cause compression. In lesions of the musculospiral nerve it was possible to divide the anterior fibers of the median nerve, with but temporary loss of sensation, and to transplant the peripheral segments of the other nerve, as a healthy nerve was a good medium for the downgrowth of neuraxes. The nerve sheath had to be sutured with fine sutures. The susceptibility of the nerve trunks to stretching had been made use of to bridge defects. The damaged portion was removed, the healthy ends connected with silk, and the limb was then put in flexion and day by day for some weeks was gradually extended, until it was little by little brought into the straight position without undue tension on the sutured nerve. The preservation of healthy fasciculi was the prime essential of good nerve surgery. If these were embedded in scar tissue, the prognosis was bad. The nerve should be grasped with very fine forceps and removed by very small portions, so as not to risk sacrificing too much nerve tissue, and the ends should be approximated by single through-and-through catgut suture. The autograft method had produced many successful results, and when necessary the internal cutaneous nerve could be sacrificed to supply the graft. Recovery of function took longer after grafting. Tendon transplantation could be resorted to to replace paralyzed muscle, and in these cases electrotherapy had a most successful effect on the patient's psychology; it interested him and he felt that something was being accomplished in the tedious interval. Baths could be used to prevent keloid formation. The curative workshop had a physical and psychological value in the gradual restoration of function which might take six months to two years. It was necessary that the muscle be kept in a state of absolute relaxation, and cases in which proper splinting had been attended to got well sooner. The plaster cast was undesirable as it promoted the formation of ulcers and, being heavy, prevented the patient being an ambulant case, which he often could be. Treatment was designed to keep the patient busy every hour and minute of the day, and a schedule was planned so that the physician could see at a glance what the patient ought to be doing at a certain time, and if he were faithfully following the course of therapy outlined or not.

Chronic Osteomyelitis Resulting from Gunshot Injuries.—Major EDWIN W. RYERSON of Chicago presented this paper. The speaker said that of 5,000 overseas cases received at Fort Sheridan, 700 were of chronic osteomyelitis. This was the result of Chateau Thierry and the battle of the Argonne Forest. The injuries were of 6 months' duration and usually caused by high explosive shells. In cases where an 18 mm. bullet was the projectile, the agent passed clean through the bone and tissue, leaving a perforation which did not give much trouble. Fracture cases were not operated upon unless there was marked laceration. In cases in which wide debridement was done and the Carrel-Dakin technique used, the infections seemed to be limited to the immediate vicinity of the wound and did not extend to the medullary cavity, on account of the lack of tension of the medulla, due to wide opening of the wound. Sequestra were usually present and these had been apparently left in the wound, in the hope of consolidation of fragments of the fracture. The rule had been to leave any fragments with periosteum attached, but later it was impossible to tell whether these sequestra had been attached to periosteum or not. The limb usually presented a swollen discolored appearance, with old, healed scars. *X*-ray examination disclosed the pathology—the presence of sequestra, with necrosis of bone—and the neighboring bone had undergone the atrophy of degeneration as the lime salts had been carried away by the blood stream. The *x*-ray plates needed careful interpretation. There was often disclosed a hole in the bone that showed no tendency to heal, a sort of cave with overhanging edges which acted as a septic pocket. The infection was a low-grade staphylococcus contamination, the cases being apparently on the verge of healing, and yet they did not heal. These cases were of very great interest, although there was nothing new or startling in their treatment and many old phases of treatment had been rediscovered. One was the use of chlorine as an antiseptic and the other was the value of the use of flaps. The technique consisted of removal of all sequestra and the overhanging walls of the bone cavity. Incision down to the periosteum was done, avoiding the exposure of more bone than was abso-

lutely necessary. The periosteum was scraped away and the necrotic bone chiselled. "Give the poor bone a chance" was a good dictum, as the bone needed all the nourishment it could get. Half the bone might have to be obliterated and the soft parts should be let freely into this area. Most of the bleeding would be papillary oozing, which had to be packed tightly. The use of carbolic acid or iodine was interdicted, and weak Dakin solution was used to cleanse the wound. It was wise to apply a wire splint before operation and to keep it in place during the procedure. In cases of virulent infection it was wise to use the Carrel-Dakin method, and not to close the wound until the bacterial count came down. One hundred and fifty cases at Fort Sheridan had been treated according to this method. A light dressing was laid around the wound, but not over it, and it tended to fill with healthy granulations. Sunlight, and when this was not possible, electric light, were allowed to bathe the wound freely. Position was of importance and the patient was made to lie on his face so as to let the pus flow out of the wound, instead of, as was so often done, allowing a pool of pus to collect in the wound. As healing took place, the skin was drawn into the deeper parts of the wound by strips of plaster, and sometimes muscle and fascia had to be put into the wound.

Loss of Bone Substance and Non-Union Following Gunshot Injuries.—Major F. H. ALBEE of New York made this presentation, which he illustrated by lantern slides showing the substitution of grafts of bone and plastic addition of soft parts, for losses of tissue which had been carried away by high explosives. In any cases where it was possible to leave bone fragments, Dr. Albee said that this should certainly be done, as this avoided the bone-graft operation. Many cases put down for bone graft were restored spontaneously because of fragments left as osteogenetic centers. In cases of extensive loss of bone, operation should never be undertaken until complete healing of the soft parts had taken place for a generous period of time. If there was no infection and the wound had healed kindly, then three months was a good time to allow for waiting. If safe to do operation then, it was better to do so, because then there would be less loss of function than if one waited longer. The limb should be allowed free motion without splints in order to stir up any latent infection that might exist, and if necessary, the operation could be further postponed. In regard to operation, as soon as the graft was in place, the wound should be closed, so as to expose the graft to the air as little as possible. High speed in the operation should be tried for, and this could be attained by the use of the electric twin saw. The operation had been done in as short a time as 19 minutes, but it averaged 30 minutes. Long drawn out operations of two or more hours were sure to spell trouble. Cases of non-union after the use of the Lane plate had been seen, although the apposition of the bones was excellent, and the reason for failure was undoubtedly because the screws tended to hold the bones apart and to obliterate the thrust of one bone upon another which was the necessary stimulus for osteogenesis. Normal growth of bone took place by a simultaneous stimulation of all the layers together. The osteogenetic cells acted in some way upon the fibrous tissue and turned it into bone, and this accounted for the rapid union in the case of green-stick fractures. In joint work the graft could be pushed well into the cancellous bone and a favorable take of the graft could be expected. A graft could be put in to stand stress, provided the fixation at time of operation was right. Stress was the greatest stimulus to bone growth and without stress the cortex became paper-shelled, which state was avoided by the grinding of one fragment on another, sclerosis of the bone resulting. In grafting it was important to restore the marrow cavity from one fragment to another. The gutter should be made deep enough so that marrow fragments would cling to it. In arm fractures it was necessary to get back to healthy vascular substance; the bleeding might be tiresome, but this was an essential point. Grafts of the long bones could be made with mortised ends so that there was a good shoulder for the graft to rest on and better thrust was obtained.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

VIRGINIA STATE BOARD OF MEDICAL EXAMINERS.

Richmond, June 18-21, 1919.

(Concluded from page 852.*)*

SURGERY AND GYNECOLOGY.

1. Give symptoms and physical signs of empyema.
2. What are the conditions necessary for successful skin grafting, and what is meant by the terms autograft and heterograft?
3. Differentiate cholelithiasis, gastric ulcer, and right renal calculus.
4. Differentiate glaucoma, iritis, conjunctivitis.
5. What symptoms follow injury to the musculospiral nerve below the branch going to the supinator longus muscle?
6. What important structures lie near the femoral ring?
7. Give clinical history and diagnosis of acute osteomyelitis.
8. Differentiate ovarian cyst and tubercular peritonitis with effusion.
9. Give causes and treatment for cystocele.
10. Differentiate tubal pregnancy and acute salpingitis.

MEDICAL JURISPRUDENCE, HYGIENE, AND PREVENTIVE MEDICINE.

1. Define "rigor mortis" and discuss its importance from a medicolegal standpoint.
2. What points would help to determine whether a "gunshot wound" were self-inflicted? The same to "throat cut"?
3. Under what conditions is the destruction of the fetus justifiable?
4. On what points, upon examination of a suspected case, could you be certain that rape had been committed?
5. Can a man's wife who stays with him, after she knows he has gonorrhea, use the fact of his having it, as a cause for divorce? Why?
6. What is the best method of purifying water for pharmaceutical or analytical purposes? Why is this method not used to purify water for general use?
7. What is hard water? And discuss its bearing on its sanitary value.
8. What do you understand by "vital statistics"? And what is its significance from the standpoint of preventive medicine or hygiene?
9. Give the best method of fighting an epidemic of cerebrospinal meningitis.
10. What steps should be taken to get rid of malaria in a locality?

ANSWERS.

SURGERY AND GYNECOLOGY.

1. EMPYEMA.—*Symptoms:* Fever, sweats, chill, diminished breath sounds and vocal fremitus, impaired mobility of chest, dullness on affected side, heart displaced to opposite side, leucocytosis.

The *physical signs* are those of fluid in the pleural cavity; that side does not move well, the percussion note is dull, there is absence of breath sounds, vocal fremitus and resonance are diminished. Left alone, an empyema may burst through an intercostal space, usually the fifth. The lung is collapsed in extent according to the amount of pus. Aspiration shows the presence of pus.

2. *Conditions necessary for successful skin-grafting* are: Proper selection of cases and methods, rigid asepsis, absence of tension, absence of cicatricial tissue, and thorough freshening of the part to be covered.

An *autograft* is a graft supplied from the body of the patient.

A *heterograft* is a graft taken from some person other than the patient.

3. In *cholelithiasis*, the attack is sudden, the pain very severe and generally localized in the right hypochondriac region, and often spreading to right scapula and over the abdomen; vomiting. chill, fever, drench-

ing sweats, feeble and rapid pulse are common; liver and gall bladder are swollen and tender; jaundice may supervene; the urine may show bile pigment and albumin; examination of the feces for a few days after the attack may reveal the calculus.

In *nephrolithiasis*, the pain is also sudden and very severe, begins in the lumbar region and follows the course of the ureter, and is often referred to the testicle and glans penis; nausea, vomiting, chills, fever, and sweat are common; strangury may be present; there is great prostration following the attack; there may be polyuria or suppression of urine; with the aid of a cystoscope or sound, the calculus may be found in the bladder; examination of the feces is negative.

In *gastric ulcer*, the pain, while severe, is never as severe as that of biliary or renal calculus; it is localized in the epigastric region, and comes on soon after eating. There is no chill, no vomiting, no fever.

4.

ACUTE IRITIS.	ACUTE CONJUNCTIVITIS.	ACUTE GLAUCOMA.
1. Iris swollen, dull, and discolored.	1. No change in iris.	1. Iris congested, discolored, dull, periphery pushed forward.
2. Pupil small, gray, sluggish, irregular after use of atropine.	2. Pupil normal.	2. Pupil dilated, oval, immobile.
3. Anterior chamber of normal depth (deeper in serous form) and presents exudation.	3. Anterior chamber normal.	3. Anterior chamber shallow and aqueous, sometimes turbid.
4. Cornea transparent (may present deposits on posterior surface) and sensitive.	4. Cornea transparent.	4. Cornea steamy and insensitive.
5. Ciliary (circumcorneal) injection; pink zone of fine vessels surrounding cornea and fading toward fornix.	5. Conjunctival injection, coarse meshes, most pronounced in fornix and fading toward the cornea.	5. Ciliary and episcleral injection (also conjunctival congestion).
6. Conjuctiva usually transparent.	6. Conjunctiva reddened and opaque.	6. Conjunctiva congested and chemotic.
7. Lacrymation but no discharge.	7. Mucous or muco-purulent discharge.	7. Lacrymation but no discharge.
8. Tension usually normal (occasionally increased).	8. Tension normal.	8. Tension increased.
9. Some ciliary tenderness.	9. No ciliary tenderness.	9. Ciliary tenderness.
10. Pain radiating to forehead and temple, worse at night.	10. Discomfort, hot gritty feeling, but no real pain.	10. Severe pain in and about eye, with headache.
11. Dimness of vision.	11. No interference with vision, except blurring caused by the discharge smeared over the surface of the cornea.	11. Marked dimness of vision.

—(May's *Diseases of the Eye.*)

5. Injury to the musculospiral nerve below the branch going to the supinator longus muscle is followed by: Inability to extend the wrist and fingers; wrist drop, with the hand held in the position of pronation; the fingers are flexed, but the last two phalanges may be extended by the action of the interossei muscles. There is no loss of sensation.

6. The *femoral ring* has, in *front* of it, Poupart's ligament and the deep crural arch; *behind* it, the pubic bone, pectineus muscle, and fascia; on its *inner side*, Gimbernat's ligament; on its *outer side*, the femoral vein, from which it is separated by a septum from the crural sheath; external to the femoral vein are the femoral artery and the anterior crural nerve. The deep epigastric artery passes close to the upper and outer angle of the femoral ring. The femoral ring is the upper opening of the femoral or crural canal, which is about half an inch in length.

7. ACUTE SUPPURATIVE OSTEOMYELITIS.—"*Causes:* The general vitality is lowered, and there is some focus of ulceration in the mouth or throat, by which organisms enter and circulate in the blood. All that is now necessary is that some part of a bone should have its vitality depressed by a blow, strain, or exposure to cold, and the organisms then attack it. The bacteria most commonly found are the staphylococci, but streptococci are present occasionally. The disease usually begins in the new growing bone at the end of the diaphysis, rarely in the epiphysis. The lower ends of the femur and radius, the upper ends of the tibia and humerus, are the commonest seats.

"*Symptoms:* The disease begins with a rigor, high temperature, and severe pain. The part becomes swollen, infiltrated, and congested, with distended veins over it. The pulse is rapid and small and the tongue dry, and delirium soon comes on. It should be distinguished from acute rheumatism by the fact that the interarticular and not the articular region is affected. Fluctuation can be detected if the bone be superficial, or the abscess may burst on the surface. The bone is then found to be bare over the extent of the abscess cavity. When the bone is deeply seated or the disease confined to the medulla, the swelling is later in evidence, but the pain and toxemia are very severe, and the patient may die from this before local signs show themselves. When the epiphysis is attacked, septic arthritis often quickly follows, and a loose flail joint may result."—(*Aids to Surgery.*)

8. "Encysted peritoneal exudates of a tuberculous origin may very closely resemble the ovarian cyst. In many of these cases the results of the physical examination are such as to fit as well with one condition as with the other, but in general the outlines of the ovarian cysts are sharper and more distinct, and the tumors themselves are often more motile in response to the changing position of the patient. Usually there is no fluid free in the peritoneal cavity, in the case of an ovarian cyst, while this is quite common in tuberculous peritonitis. In many cases light may be obtained from other sources—the history of the case, the body temperature, the patient's general condition, her behavior under Koch's tuberculin test, and an examination of the other organs of the body. The demonstration of a tuberculous process elsewhere in the body, as in the lungs, lymph glands, or bones, speaks strongly for the tuberculous nature of the process in the abdominal cavity. A coincident inflammation of one or more other serous surfaces, such as the pleura or pericardium, also speaks for the tuberculous nature of the process. In still other cases it is necessary to make an exploratory puncture in order to ascertain the character of the fluid. If the fluid is an exudate, it will have a high specific gravity and percentage of albumin. The fluid of different ovarian cysts varies considerably in specific gravity, from 1.007 to 1.020 or more. In one case it is a thin serous fluid; in another, a gelatinous material. It contains considerable albumin and paralbumin. Microscopically there is nothing peculiar to these cysts except the cylindrical epithelium occasionally found."—(*Reference Handbook.*)

9. *Cystocele* is really a hernia of part of the bladder into the vagina, the vaginal mucous membrane forming its outer covering; or it may be expressed as a deflection of the vesico-vaginal septum toward the vagina. It forms a smooth rounded swelling, which bulges through the vulvar aperture when the patient coughs or strains. The cause of cystocele is a relaxation of the tissues forming the vaginal walls. This is mainly due to childbirth. *Symptoms:* A dragging sensation in the lower pelvic cavity; a feeling of distention at the vulva; loss of power in urination; tumor of anterior vaginal wall, more apparent on straining; prolapse of uterus. It is often accompanied by rectocele.

For radical cure of cystocele: "The patient is placed in dorsal position. The posterior vaginal wall is kept out of the way with a weighted speculum. The cervix is drawn down with a bullet-forceps. With a pair of tenacula the sides of the prominence are drawn together in the median line in order to see how much of the wall is redundant and these points are marked with small nicks. Next, the whole surface is put on the stretch between four pairs of forceps—one at each of the side marks, one near the cervix, and one at the transverse ridge at the inner end of the urethra. With a pair of scissors curved on the flat, a strip about ¼ inch wide is cut out of the mucous membrane. Similar strips are removed on both sides until an oval is denuded. Finally a running suture of chromicized catgut is passed under the whole pared surface, uniting the

edges from side to side."—(From Sutton and Giles' *Diseases of Women.*)

If necessary, a perineorraphy should be done at the same time.

10. In *extrauterine pregnancy* there will be signs of early pregnancy, hypogastric or inguinal pains, probable history of a previous sterility, probable expulsion of decidual membrane or shreds, softening of the cervix, enlargement of the uterus, the tumor is not bound down in the pelvis, presence of a distended tube, contractions of the wall of the gestation sac; if rupture occurs, there will be sudden, excruciating pains over the lower abdomen and on the affected side, shock, collapse, and symptoms of internal hemorrhage. In *salpingitis* the tubes are inflamed usually secondary to inflammation of uterus or to infection (either gonorrheal or puerperal), backache, pain in lower abdomen, history of menstrual irregularity, leucorrhea, tube is enlarged and tender, the uterus is not enlarged, the signs of pregnancy are not noticeable, the tumor is firmly bound down in the pelvis.

MEDICAL JURISPRUDENCE, HYGIENE, AND PREVENTIVE MEDICINE.

1. *Rigor mortis* is the condition of rigidity or contraction into which the muscles of the body pass after death. It begins at a period varying from about fifteen minutes to about six hours. It usually begins in the muscles of the eye, neck, and jaw; then the muscles of the chest and upper extremity, and last of all those of the abdomen and lower extremity are affected. It passes off in the same order in about twenty-four hours. It is said to be due to the coagulation of the muscle plasma.

Medicolegally, it is a sign of death, and an indication of the length of time that has elapsed since death occurred. The onset and duration of rigor mortis depend upon the previous degree of exhaustion. In death from exhausting diseases there is an early onset, while in those dying suddenly, as from accident, it may be delayed for twelve hours or more. Its duration is very variable; it is shortened by heat and prolonged by cold; it generally lasts about twelve to twenty-four hours; in death by lightning or electrocution it may only last a few hours, in other cases several days.

2. *Points which help to determine whether a gunshot wound was self-inflicted:* The location of the wound; the distance at which the shot was fired; the character of the wound; the burning of clothing, skin or hair; the embedding of grains of gunpowder; the presence or absence of the weapon; the position of the body when the wound was received; and certain surrounding circumstances which may have a bearing on the case.

In "*throat-cut*," suicidal wounds (in right-handed people) usually begin on the left side, and are directed toward the right; and except for a few scratches at the very commencement, the incision is generally deeper on the left side, and is higher on the left side, the wound being oblique from left to right and from above down.

3. *Destruction of the fetus is justifiable* and not criminal when it is due to natural causes, or when done by a physician, after proper consultation, for sufficient cause. The chief conditions that justify it are: (1) Certain pelvic deformities; (2) placenta prævia; (3) pernicious anemia; (4) toxemia of pregnancy; (5) habitual death of the fetus toward the end of pregnancy; (6) hydatidiform mole; (7) habitually large fetal head. But when performed, or attempted, for any other reason, or under any other condition, it is *criminal.*

4. *Rape* has been defined as being the carnal knowledge of a woman against her will. But the element of will may or may not enter into the case; consent, if it be obtained by fraud or from one mentally deficient, or under age, does not relieve the criminal from the charge of rape. Rape may also be perpetrated when the victim is unconscious or in such other condition as to interfere with the action of the will.

"Medical testimony in these cases has usually to do with three conditions: (1) The presence or absence of bruises, lacerations, or other signs of injury upon or about the genital organs. With regard to the evidence of lacerations of the hymen, it must be remembered that a certain number of hymens are so elastic as to permit of intercourse without laceration. (2) The presence or absence of spermatic or blood-stains upon the person or clothing of those concerned, and the presence or absence of spermatozoa in the vagina. (3) The presence of venereal disease in one or both."—(Dwight.)

The physician can *never be certain* that rape has been committed on an adult, because the element of "volition" enters into the case. All he can do is to give evidence on the lines indicated above, and leave it to the jury to decide to what extent the complainant was "willing."

5. The generally accepted rule is that if the husband had *concealed* the existence of the disease, there would be ground for divorce. The fact that his wife knew of the disease, and continued to "stay" with him, shows that she condoned the offense. If, under the condition, the husband compelled sexual intercourse, the court might interpret the same as "legal cruelty" and on this ground grant a divorce.

6. The best method of purifying water for pharmaceutical or analytical purposes is distillation; only the "middle run of the still" must be used.

This method produces a water that is flat or tasteless, being deprived of oxygen and carbon dioxide; at the same time certain volatile substances which were present in the original water may appear in the distillate and produce undesirable results. To remedy these defects is expensive.

7. A water is said to be *hard* when it contains in solution certain salts, such as calcium and magnesium salts, which form with soap a curdy deposit.

Sanitary value of hard and soft water: "An excess of limesalts and of other mineral matters in water produces constipation, flatulence, indigestion, and favors the formation of calcareous deposits in various parts of the body. 'Hard water' unites with soap and makes it less soluble, so that it is difficult to cleanse the hands with it. It also roughens the skin and dries the mucous membranes. By boiling, the hardness of water, which is due to the presence of earthy carbonates, is diminished, for the carbonic acid, which aids in holding them in suspension, is driven off. Water is also improved for drinking by filtering through a filter paper or clean absorbent cotton on a funnel. Boiling the water does not precipitate neutral and alkaline salts, and a purgative action may still remain if they are present. Hard water is made more digestible by converting it into barley or oatmeal water. Water which contains sulphate of lime causes gastric distress and dyspepsia, and it may form calculi. 'Soft water' is simply water which is free from objectionable salts. It is more wholesome than hard water. Hard and soft water have well-known characteristics in regard to their effect upon the cooking of food. Calcareous drinking waters have been believed to be factors in the development of goiter and cretinism, notably in Switzerland, but many cases occur in which such theory is untenable."—(Thompson's *Dietetics.*)

8. *Vital statistics* is the science of figures applied to the health history of countries, and the study of the laws that govern the physical condition of the inhabitants. It deals with births, marriages, and deaths, the diseases from which we die or suffer; and it takes into consideration the age, sex, and occupation of individuals. The study of vital statistics gives information as to the health of the people in a community, and to the good and evil conditions present; it shows the fatality of different diseases at different ages; it indicates the influence of professions, trades, locality, and age on the well-being of a community; and it enables the authorities to estimate whether conditions are improving, from a sanitary standpoint.

9. *To fight an epidemic of cerebrospinal meningitis:* Isolation of all known cases, and also of suspected cases, with report of the same to the health authorities; education of the public as to "carriers," and spread of infection by the nasal secretion; the use of antiseptic gargles and nasal douches; antimeningitis serum has also been recommended.

10. *To get rid of malaria in a locality:* Individuals should use mosquito netting round their beds and wire gauze in doors and windows, so as to keep out the mosquitos as much as possible. During residence in malarial districts quinine should be taken every morning before breakfast. All pools, stagnant water, etc., where *anopheles* may breed, should be removed. All mosquitos, larvæ, etc., should be destroyed as far as possible. By staying indoors during dusk and darkness, opportunities for infection may be avoided. Occasional fumigation with formaldehyde or sulphur is useful.

OCCUPATION THERAPY AND TUBERCULOSIS.

By W. R. DUNTON, Jr., M.D.,

TOWSON, MD.

PRESIDENT OF THE NATIONAL SOCIETY FOR THE PROMOTION OF OCCUPATIONAL THERAPY.

At a recent meeting of the National Society for the Promotion of Occupational Therapy, held in New York, I received a letter from which the following is extracted. In preface it may be said that the writer was born August 30, 1837, holds the degree of Master of Arts from Yale, has been a professor of chemistry and geology, and has attained eminence as a mining and metallurgical engineer. The letter is dated at Colorado Springs, August 29, 1918.

Miss Susan S. Harris, R.N., Director of the School of Diversional Occupations in our city, has asked me to write you. On such short notice, I do not know that I can do much more than congratulate you and the society on having such a capable, faithful, and efficient representative here in the person of Miss Harris; also to congratulate you on your great humanitarian work, in lending the word of cheer, the ray of hope, the hand of help, to the great multitude of those struggling with limited means against the tubercular blight. The cure is largely a mind cure.

If one is going to get strength, even with exercise, he must get it from his food; and it will not come from his food, unless that food digests; and it will not properly digest when the mind is in a constant state of anger, or worry, or despair. I say this as a chemist who has devoted much time to analyzing contents of stomachs. In Colorado the rest fad is in the saddle. The objection to it is that the feet and legs get rest, waste away in flesh and strength, while the upper portion of the body, which ought not to be subjected to strain, gets more unwarranted exercise in one hour, in the majority of cases, than it should have in a week. Within the past few months I have carefully studied some forty cases of those taking the so-called "rest cure." Not one case, where I have remained longer than twenty minutes, that the rester has not taken a straining exercise ten times more violent than he would have taken in an easy chair or in walking about his room—ten times the amount of exercise that I was taking during my visit. There was a reaching for sputum cup, reaching for water, pouring out water from a pitcher, twisting the whole body in fixing the pillow, pulling up bedcovers, with hands on bed lifting himself up into a sitting position, etc.

One great objection to the so-called "rest cure" is that it gives too much time for thinking about personal ills, personal troubles, the wasting of time, the uncertainty of the future, financial difficulties, home responsibilities, and meditating on the dark clouds, sure forerunners of despair. All of which have a depressing effect on the mind. In such cases, even if a cure is effected, in nine cases out of ten, blasting habits have been formed which leave the cured either mutton-heads or social parasites.

When I left Yale College in 1865 I weighed 178 lbs. When I came to Denver in the early part of 1874 I weighed only 119 lbs. I had been examined by three physicians in St. Louis. They all told me I had waited too long. One told me that I would never reach Denver alive. At Denver I was taken from the depot on a stretcher. Twenty-two days passed before I was able to sit up. When I was able to move about I took all the judicious exercise I could. Never thought of giving up study and teaching and geologizing. Like thousands of others then, I could not afford to be idle. Could not afford to die. For six years I worked and fought consumption. Did it so effectively that ten years after coming to Colorado I called on the St. Louis doctor who said I never would reach Denver alive. After examining me again he said: "Well, at that time I told you the truth, but you were too stubborn to die."

Am now satisfied if I had taken the present so-called rest cure forty-four years ago, I would have to-day a record of over forty years in eternal rest, instead of a record of eleven years in the tropics, one year in England, one year in Germany, and one year in Japan and China.

In those days we had a greater proportion of cures in Colorado than we have to-day. Surely it *cannot all* be due to the fact that we had but few doctors then to kill us. My firm opinion is that it was our ignorance of the so-called rest cure and our own blundering on to lines of occupational therapy that saved us in those far-away days.

To-day Occupational Therapy is the only fadeless candle in the window for the unfortunate T. B.

Very sincerely and cheerily,

K———

A number of comments may be made on the foregoing. In the first place it may be at once admitted that the rest cure as described is not a rest cure. Years ago, practitioners attempting to give the Weir Mitchell rest cure for nervous invalids met with poor success. Later it came out that while the patient was placed at rest physically his mind, and especially his attention, was not permitted to be idle. He was diverted by being read to, massaged, bathed, fed, and talked to, until the depressing or fatiguing thoughts which characterized his illness were forgotten. When carried out with proper attention to the morale or mental attitude of the patient the rest cure was successful. A special nurse was therefore absolutely necessary. As described by Mr. K. evidently there was no special nurse to pour the water, pass the sputum cup, or arrange the pillows. It can easily be conceived, therefore, that a patient in a reclining chair, who is not the sole charge of a nurse, may be able to get more rest than when recumbent in bed, because less movement is required for necessary reaching.

We pass over Mr. K's remark about there being "few doctors to kill us" as being a bit of airy persiflage. His remarks about too much time being given "for thinking about personal ills,

etc.," apply equally well to many other conditions and it is believed that insufficient attention is given to the patient's mental attitude by the majority of physicians. In the introductory chapter to "Pulmonary Tuberculosis and Sanatorium Treatment" Dr. C. Muthu says

It is not by injections and inoculations that the final triumph over disease will be achieved. Vaccine and serum therapy are only a half-way house at most. We have many leagues yet to travel to reach the goal of medicine, viz., the prevention of disease. Evolution is moving humanity forward from cruder to higher life, and the physician should keep pace with the times, and equip himself with more and more refined methods in his treatment of disease. Already our remedies have changed from cruder to finer forms. Bleeding is gone, drugging is going; electric treatment, with all the mysterious forces allied to it, is already to the front, and psychic treatment is coming forward for serious consideration. No treatment in the future will be deemed permanent or satisfactory which does not recognize the psychic element of man. The ancient Brahmins combined in their persons the offices of physician, philosopher, and priest, which represent the functions of the body, the mind, and the spirit. We are just beginning to tap the mind forces in the treatment of disease, and the spirit forces are still beyond. If the medical profession would lead humanity aright in the future, as it has always done, it would not be content to live in the lower planes of physical treatment, which is cramping its sphere and usefulness, but would rise with the trend of the times, and learn to make use of those psychic and mental powers for bringing about the healing of body and mind.

"What has all this to do with tuberculosis and the open-air treatment? A great deal. Behind the visible factors that make for consumption lie the root-causes of worry and anxiety, of mental strain and fatigue, of restlessness and instability. And it is only by bringing calm and peace to mind and body that disease can be tracked to its deepest lairs and be destroyed. Peace and calm of mind spell health of body. This is why we read that the Great Master healed the body by speaking peace to the inmost soul. The civilized man has lost the secret of peace. While he has multiplied riches and comfort, he has also multiplied care and disease. *And open-air treatment has taught this precious lesson—that it is only by going back from the bustle and excitements of town life to the calm and communion of nature that man will regain his lost peace and health.* The secret of the real strength and happiness of an individual lies surely in the simplicity of his life and the fewness of his wants.

If mankind is to progress in the future towards the achievement of its ultimate aim—the prevention of disease—it will move in the following directions: It will strive towards removing all those evil conditions which predispose the body to disease. This creation of a healthy environment by return to nature and to a simple life will enable the forces and powers of the mind to exert their healthy control over the activities and functions of the physical body, and the harmonious working of body and mind will bring about peace and health. The open-air treatment has given a right lead in this direction. If man would only learn the full meaning of the movement, and follow the footsteps of nature in humility and reverence, it would lay a foundation for a great reform. It would bring about a revolution in the social and national life as momentous and far-reaching as the idea of evolution created in the scientific world.

After such an expression of the importance of the patient's mental attitude it is naturally to be expected that Dr. Muthu would amplify the subject in his later description of treatment. Excepting for a number of remarks about vital energy, previous to the above quotation, in which he states that for a free flow of vital energy the body should be kept in good repair by food, and the mind should be undisturbed, with slight further elaboration of these statements, there is nothing more found upon the subject of the mental attitude.

No directions are given for invalid occupation or occupational therapy. Directions are given for walking exercises, breathing exercises, singing exercises, reading exercises, manual exercises, and tramping, etc. An interesting comparison is afforded of the pedestrian habits of the English and Americans, by the following directions for manual exercises.

When the patient is able to walk about four to five miles a day, and the temperature is satisfactory, he is allowed to do some manual work for about twenty minutes, which is increased to forty minutes, and then to an hour a day. There are three grades of work:

First Grade.—Weeding in the garden, hoeing, raking, and gathering leaves, edging grass, planting, pruning, etc.

Second Grade.—Chopping logs, making paths in the woods, spade-work, digging broken ground, etc.

Third Grade.—Sawing, carpentering, painting, digging unbroken ground, wheelbarrow work, etc.

Ever since manual labor was introduced in this sanatorium as part of the treatment a decided improvement has been noticeable. During an experience of more than five years we have had no untoward result except in two instances, when the temperature rose after the exercise and continued for some days after, which showed that the patients had overexerted themselves.

It may be stated here that while a rise of temperature is usually noted after physical exercise, it should return to normal after an hour's rest. The exercises as noted seem somewhat strenuous and various forms of craft work might be given earlier with benefit.

Elsewhere it is said that patients walk for an hour and a half in the morning and for the same period in the afternoon, and for a half hour before breakfast and after supper, "When he covers about eight or nine miles during that time." It is believed that few American men in good health walk so much as this during the day's activities.

Another writer, Bonney,[2] also refers to the psychic element and says (p. 757): "It is essential that *recreation* be *combined* with *exercise.*" Also "correctly regulated exercise, if adapted to the inclinations of the invalid, is diverting in nature and correspondingly healthful, while physical effort *without recreation,* no matter how perfectly adjusted, remains but work, and hence less advantageous."

In a much older book,[3] Dr. Thomas J. Mays says: "It is of the highest importance to keep in mind the fact that whatever the mode of physical exercise may be, it must not be compulsory, but must be performed without effort, and, as it were, without consciousness." Though less clearly expressed, a thought similar to Bonney's, that is, that the patient's mental attitude will determine the benefit derived from physical exercise.

In a brief address made before the American Society of Superintendents of Training Schools for Nurses in 1910, Dr. Livingston Farrand states that "Work under the strict supervision of the Medical Superintendent is one of the most valuable factors we have; the patients almost invariably do better." He speaks of cases from the Yonkers carpet mills who have done better when they have been allowed to return to their former work. In this, evidently the patient took

a greater interest than in the new work which had been found for him. Dr. Farrand also speaks of a "growing tendency" to provide some sort of occupation for patients when discharged. Surely a step in vocational education.

Dr. Lawrason Brown has written some excellent Rules for Recovery from Tuberculosis[4] which deserve to be better known. In the chapter on Exercise he says "Exercise is as important as rest in the treatment of pulmonary tuberculosis but vastly more dangerous." He directs attention to the fact that the small duties of life, such as dressing, entail considerable exercise, therefore they must be taken up carefully. In this book, "Exercise means walking. Special permission must be obtained before indulging in other forms of exercise." Another excellent chapter is "On Cultivating an Outdoor Hobby and on Recreation." It seems unfortunate that but few directions or suggestions are given for mental occupation during the long periods of resting. Reading and writing are merely suggested by being forbidden during a certain period. Bird study by means of an opera glass, the study of botany from specimens brought by friends, sewing, knitting, and crocheting, and solitaire are the only occupations specifically mentioned. All of these require some movement. It would seem that puzzle pictures, embroidery, some forms of knotting, and clay modeling, would not entail as much physical exertion as does the lay-out of solitaire. If reading can be permitted there is a splendid opportunity to provide subject for thought even while at absolute rest, and if worry and anxiety is replaced by speculations upon art, history, or biography there is no doubt that the rest will be more beneficial. Courses of study, if not carried out too enthusiastically, might be undertaken. "Cerebral activity is as great a drain on the patient's vitality and reserve force as is physical exertion." In the tuberculous especially, it seems advantageous to permit the patient to undertake some work allied to his former occupation, as there may be less depression and anxiety if he feels that he is still linked to his old job.

Dr. Philip King Brown, has interestingly described the Potteries of Arequipa Sanitarium,[5] and from the fact that but 24 out of 66 made good and 20 of the 24 had previously been successful, has come to agree with the theory of the psychological determinists: "How many things and how hard things a person will do lies in his nature; the kind of work may change but there is no new potential." All of the patients in this sanitarium were wage earning girls.

Dr. Horace Carncross,[6] believes that the mental change noted in the tuberculous is due to chronic illness rather than to tuberculosis specifically. This view would appear to be correct.

Dr. Guy H. Fitzgerald has very fully considered the Mental Side of the Consumptive[7] and says: "Mental content is as necessary in successful treatment as pure air and good food."

How then may mental content be secured? And what occupations shall be given? To secure mental content we must study each individual patient, and adapt our means to him. His physical condition must first be considered, next, his capabilities, and finally his tastes or interests. With these three siftings the best means will be found.

Before answering the next question it may be well to consider what work does to the tuberculous patient. The work of Walther of Nordrach, Patterson of Frimley, and McConnell of Colorado Springs has shown that physical exercise causes a discharge of toxins into the circulation with consequent autoinoculation of the patient. As is well known, immunity to a disease is secured by gradually increasing the strength of inoculations. Patterson claims that by gradually increasing the work we increase the strength of the autoinoculations until immunity or cure is finally reached. Less enthusiastic advocates, or opponents, of the work cure object that there is no possibility of gauging the amount of dosage as the amount of toxin liberated by a given amount of work will vary in different individuals, and it is therefore dangerous. According to McConnell[8] in febrile cases the autoinoculations are excessive and must be reduced by appropriate means. He treats such cases by absolute immobilization in bed, as a typhoid patient is treated.

The patient is not allowed to move in bed, to read, to wash himself, to cut up his food, or to go to the lavatory. If rising from the bed or moving about do not produce a rise in temperature a preliminary period of walking exercise is prescribed. In this paper Dr. McConnell does not touch upon the mental side and it is easily conceivable that bed occupations are permitted before the walking period, but mention of them has been omitted.

During the past year an investigation of Invalid Occupation, Principally at Sanatoriums for Tuberculous, was made by Mr. T. MacLaren, an architect of Colorado Springs, who while a patient at Davos Platz and Saint Moritz, found sketching out of doors "a most agreeable substitute for idleness." In his study, as in the majority of papers on the subject, much more attention is given to ambulatory occupations than to those which may be given to the "resting" patient in bed. It appears that more should be published on this part of the subject. Captain J. R. Byers, C. A. M. C., commanding the Laurentian, Laurentide Inn and St. Agathe des Monts sanatoria, says that it has been possible to allow, under careful regulation, bed patients to draw, embroider, knit, crochet, do cardboard work, and study, all in moderation. It would seem that less effeminate occupations of the same physical value might easily have been found for men.

Captain Byers' conclusions are of interest and follow:

1. That properly regulated, and the greatest care having been exercised in the selection of the work as adaptable to the patient having been made, and with a willing co-operation on the patient's part, work is highly beneficial to the patient with pulmonary tuberculosis.

2. That even Class "A" patients (bed cases) appear to progress more rapidly when allowed to fill out their day in part with some interesting finger work, rather than lie still and in all probability brood over their sad lot.

3. That contrary to expectation, relapses have been very rare (less than 2 per cent.), and that in a year there has only been one small hemorrhage following exposure in the workshop.

4. That the vocational training, while not by any means making a man a wage-earner in a new field, has in a large number of cases started new lines of thought regarding the life to be led by the patient following discharge from the sanatorium, stimulated not a few of the younger patients to improve themselves in knowledge, and a desire to rise above the level which they occupied in society before enlistment, and to become better and more useful citizens than they otherwise would become. In addition the work has made an air of contentment and happiness in the sanatorium. Generous competition has grown up among the men as to the finish and design of the work in hand. Married men have made their children happy with many novel toys and models of furniture, while many a wife has been gladdened by the production of excellent house furniture resulting from her husband's handiwork.

5. The morale of the men has improved in a remarkable manner, there is far less tendency to drunkenness, absence without leave, and more serious attention to the routine of the treatment is exhibited now as compared with those dull days previous to introducing the system.

6. The results of treatment, while not showing any marked change from those obtained in civil sanatoria, are decidedly better than obtained during the first year of military work, and comparing the large percentage of men who refused treatment last year, with the very small number now applying for releases is one of the strongest proofs of their appreciation of this method of loosening nervous tension and making the prolonged and tedious treatment bearable.

I am firmly convinced that in the application of properly regulated work of an interesting nature in the treatment of pulmonary tuberculosis we have added a fourth word to our code which should read *rest, fresh air, good food, and work.*

A number of other works on tuberculosis which have been examined give nothing which has any relation to the mental side of the patient, or to this question of the occupation of bed cases. There are numerous articles on the subject of work after leaving the hospital.

I have discussed the occupation of the tuberculous on numerous occasions with Dr. M. F. Sloan, Medical Superintendent of the Eudowood Sanitarium, and the following may be considered as a summary of our views. It is quite obvious that individually we view the subject from different view points, Dr. Sloan giving first consideration to tuberculosis, while I, from training and experience, am influenced by consideration of the mental factors. That we have been able to pool our experience and agree upon the subject will anticipate any criticism that either one is lacking in a full knowledge of the subject. For years past the Eudowood Sanitarium has been well known for the occupation of ambulant cases, and its farm is quite celebrated.

It is possible to divide the tuberculous into four groups:

1. Those who show signs of the disease with but few symptoms, who usually recover quickly, but who are difficult to impress with the necessity of sanatorium care.

2. Those showing signs and having symptoms sufficiently marked to make the patient feel that he is sick.

3. Those having extensive signs and symptoms. Who have probably been treated for other ailments, the early diagnosis having been incorrect. Who frequently have a temperature of 101°. Who are desperately anxious to get well and therefore willing to cooperate.

4. The old chronics who come to the sanatorium as a last resort for treatment, or to die.

It must be emphasized that each case is an individual problem and requires special study before any occupation is prescribed. This is one of the principles I formulated in a paper read before the National Society for the Promotion of Occupational Therapy, which were indorsed and expanded by a committee appointed to consider the subject. It is quite possible that a considerable number of cases may be exceptional, and cannot be treated as are the majority. For example, a man with a very active mind who has been accustomed to doing many things may find it extremely difficult to cooperate with the requirement of absolute rest. This may be more frequently the case with those patients in Group I. It is with such that I claim that better rest is secured if the patient is allowed for a part of the day to read or carry on some other employment, entailing a minimum of physical exertion. In this way mental rest will be secured, there will as a consequence be less motor restlessness, and therefore greater physical rest.

It is well known that the more absolute rest a diseased part is able to obtain, the more quickly will it recover. This applies equally to other organs than the lungs. The only method of giving a lung absolute rest is by producing artificial pneumothorax. It is obviously impossible to produce this on both lungs, nor is it desirable to produce it at all except in certain selected cases. Our absolute rest in bed for the tuberculous is a compromise and merely reduces the necessary functioning of the lungs to a minimum, by reducing the amount of physical exercise and the consequent necessity for an increased amount of oxygen. There is probably no greater inciter of motor restlessness than mental worry or anxiety. Those who have had the experience know this—and who has not? Even in calf or salad days we pace the floor to relieve mental tension. The man or woman who has recently been told that he or she has tuberculosis, who perhaps is somewhat doubtful of it, who is responsible for the welfare of others, who is ambitious, cannot help feeling anxiety and worry. Depressive ideas will usurp the focus of consciousness and it will be most difficult, well-nigh impossible, to lie abed and get absolute rest. It is this type of case that we feel may be best helped by reading, crocheting, whittling, knitting, sketching, writing, embroidery, or other occupations which entail a minimum of physical exertion, yet require a concentration of attention and therefore exclude the depressive ideas. I believe that bed occupations may be beneficial to the first and second groups which are noted above. It is doubtful, excepting in rare instances, if in either of the latter two groups that bed occupations may be of value. In the first place individuals with a temperature of 101° usually feel too sick to desire occupation, and depressive ideas caused by unfulfilled responsibilities will be forced to the background by the physical ill feeling.

The subject of occupations is undergoing considerable investigation at present. Let us hope that some research will be directed to the subject of bed occupations for the tuberculous.

SOME EXPERIENCES WITH U. S. A. BASE HOSPITAL NO. 37, AMERICAN EXPEDITIONARY FORCES.*

By HENRY MONROE MOSES, B.S., M.A., M.D., F.A.C.P.,

BROOKLYN, NEW YORK

ATTENDING PHYSICIAN, KINGS COUNTY HOSPITAL; ASSISTANT ATTENDING PHYSICIAN, NORWEGIAN HOSPITAL AND THE HOSPITAL OF THE HOLY FAMILY, BROOKLYN, N. Y.; FORMERLY LIEUT. COL., M. C., U. S. ARMY, CHIEF OF MEDICAL SERVICE, B. H. NO. 37.

THE entrance of a civilian doctor into army life leads to experiences both numerous and varied. His comfort or discomfort is in a large measure dependent upon his point of view and his adaptability. As the greater number of Americans can readily conform to new surroundings and conditions, we find that little difficulty is experienced and the new mode of living is soon adopted. Each individual learns that his interests are those of the organization to which he belongs and all his efforts and energies are directed toward making his Unit the most efficient in its line. The Medical Corps of the United States Army was striving for the best—our Unit was a Base Hospital Unit—and our efforts were to have our hospital give the most efficient service to the sick and wounded.

When entrance into the World War by the United States seemed inevitable, the Medical Board of the Kings County Hospital, Brooklyn, N. Y., offered this hospital to our government for use and also volunteered a base hospital unit from the members of the visiting staff and associates.

After the declaration of war by the United States, the unit was formed for overseas service. The organization was originally that of a 500-bed hospital; later this was increased to a 1000-bed hospital. We were all new at this line of effort and the greatest credit is due our Director, Doctor Edwin H. Fiske, of Brooklyn. Through his untiring energy and activity the Brooklyn Chapter of the American Red Cross with its Local Branches, and the public spirited citizens of that City, made it possible for us to obtain the necessary equipment for, at that time, the government did not accept any Red Cross Unit until it was fully equipped. Before we sailed for overseas service we were made a government hospital and all our activities were under the United States Government.

*Read at the meeting of the Medical Association of the Greater City of New York, May 19, 1919.

Many unexpected discouraging incidents and events happened during our preparation for service and in our enthusiasm to be doing something overseas, the time seemed long before we received our orders to sail. Eventually our efforts were rewarded and after two or three days of the greatest secrecy we sailed from the Crescent Athletic Club Dock, on the Shore Road, Brooklyn, to the pier and boarded the S. S. *Lapland.* The following day, May 19, 1918, at noon, the boat left the dock and we at last felt we were started on the great adventure. Our first orders were: that as soon as the boat leaves the pier everybody must go below decks: for no troops must be seen on transports until they are outside New York Harbor. We were also ordered to wear our life preservers at all times except when in the dining room and while sleeping. For twelve days our convoy of fourteen camouflaged ships zigzagged across the Atlantic Ocean escorted by the U. S. Battleship *Montana.* When about 500 miles off the coast of Ireland we were picked up by a convoy of eight destroyers and, unless one has actually had this experience, it is impossible to imagine the feeling of relief and security we had when we sighted these little boats. They sailed in and out among our vessels like shepherd dogs guarding a flock of sheep. A perfect day's sail up the Irish Sea, where many more destroyers and observation balloons came out to meet us, brought us to the Canadian Docks at Liverpool during the night. We were all glad that this phase of the journey was over for, although we did not see any immediate signs of danger, no one could ever tell just what might happen.

Our first news of the war on landing was bad news—all England felt that the Channel Ports and even Paris would soon be captured and were almost reconciled to it. The attitude of the people was one of the greatest depression and with good reason too. Every family had lost at least one member; all business was being carried on by women and old men, and everyone was underfed. A strict rationing system was being enforced. The principal meat was pork, and poor pork at that. Butter, sugar, cheese, or milk could not be had. Eggs were obtainable at prohibitive prices. No fowl or green vegetables, excepting cabbage and sprouts, were available.

We were all anxious to be in France and when we entrained for Southampton we felt that at last we would soon be caring for our own wounded. We had in store for us, however, something which at that time seemed the greatest possible disappointment. After most of our baggage had been loaded on the Packet for passage across the Channel from Southampton, we were informed that our Government had decided to establish Base Hospitals in England for the care of our troops and that we had been assigned to one of them. Nothing that I can ever write will express the disappointment of the members of our unit at that time. Never have I seen so disheartened a group of individuals as we were when we received this news. We were then ordered to the Rest Camp at Southampton and three days later were sent to a British Training Camp, turned over to the Americans, two miles north of Plymouth, England. This was

an excellent training camp of about sixty huts situated in the Southwestern part of Devonshire, one of the beautiful spots of England. But there were no attractions in it for us because we knew that it would be impossible to establish a base hospital there. I will not dwell upon our six weeks' stay at Plymouth except to say that we were all discontented on account of the enforced inactivity in hospital work. During this period many of our doctors and nurses were loaned to the British Government as there was great need of them.

At last orders came that we were to proceed to Dartford, and all our energies were directed toward a "quick get-away." Our supplies, which had preceded us by a month from the United States, had arrived in France. These were sent to Plymouth and again reshipped to Dartford when we finally established our hospital there.

Dartford is a manufacturing town of some 10,000 to 15,000 inhabitants in peace times, but of 50,000 in war times, chiefly composed of munitions workers. It is located about twenty miles southeast of London and forty-eight miles from Dover. The town's history dates back over a thousand years and it is of interest because it was the first stop made by the pilgrims when on their journey to Canterbury to visit the tomb of Thomas à Becket. It was also the home of Wat Tyler. It is five miles from Tilbury Dock, from which point many of our boys were shipped home. It is near the town of Cobham and the Leather Bottle Inn, made famous by Dickens, and also the City of Rochester, well known in early English history. Vickers Munition Works, the largest factories in England, are just outside the town, and the Woolwich Arsenal, also the largest in England, was only five miles away. Both of these places were objectives in the air raids over London, as they are in direct line to London, and several hostile machines were brought down in the neighborhood. However, we saw nothing of the Boche machines during our stay.

The hospital which we took over had been built for about twenty years and was one of the Metropolitan Asylum Board Hospitals. It was originally intended for the care of convalescent communicable diseases—cases from the City of London. It was a well-built, well-equipped plant, covering 170 acres, and beautifully situated on a hill. There were about forty buildings on the grounds, twenty-six of them were used as hospital wards—the others for administration, laundry, kitchens, storage and quarters for the personnel. We had a complete laundry, kitchen, engine room, baths, storehouses, and offices. Twenty of the buildings were built of brick and were two-story, arranged in the arc of a circle, standing alone, and could be completely isolated. Each building or block would accommodate from 100 to 110 patients and could be divided into six independent wards of different capacities. There were two small rooms for the suspected infectious diseases, a small kitchen, linen room, a nurse's office, and two baths in each block. Each building had its own hot water system and we always had hot water supply night and day.

At the time of the signing of the armistice we had a colony of our own on this 170-acre hospital —2077 patients, 42 officers, 100 American trained nurses, 225 enlisted personnel, about 50 British nursing helpers, and 200 other British helpers in the offices, kitchen, garage, laundry, and grounds. This made our hospital a town in itself and there is much more than medical and surgical work in having an organization like this run smoothly.

Our Quartermaster Department was busy and efficient. Our enlisted personnel had been carefully chosen to include clerks, accountants, stenographers, and men who could adapt themselves to different duties as well as those who would be useful in caring for the patients. We had our own carpenters, plumbers, and mechanics. All repair work, all of our food supplies, hospital dressings and equipment, transportation of our wounded, and the payment of everybody, not only our own men but also the patients were attended to by our own Quartermaster.

A 2000-bed hospital, with 60 per cent. of the patients surgical cases, requires a great amount of detail work. No patient was discharged without his necessary papers or without complete equipment and part of the pay due him from the government. All patients returning to the United States were inspected by an Inspector from Headquarters for both equipment and physical condition before leaving the hospital.

The Registrar's office was a busy spot because there seemed to be an indefinite number of different records and copies to be made and kept for the army as well as complete individual histories and records. Next to the Quartermaster Department this was the busiest office in the hospital.

The feeding of all this army of people was quite a problem. A large central kitchen was worked to its utmost capacity to provide for the patients, nurses, and British helpers. An improvised military kitchen provided for the enlisted personnel and a smaller kitchen served the officers. All the food was obtained from the British Quartermaster Department. A few additional luxuries we obtained in the open market—one month we bought $12,000.00 worth of extra milk and eggs for the patients—this coming out of the hospital fund. Had it not been for the service of the British women in the kitchen as well as in other departments of the hospital we would have been in the greatest difficulties.

We received our first patients July 29, 1918, ten days after opening our hospital at Dartford, although our British friends told us that it would take two months to get the place cleaned up and the buildings arranged for army patients. This rapid cleaning and fitting up of the hospital was the result of hard work on the part of every member of the Unit and a desire to get under headway. Our first patients were Americans who had been fighting in the North of France with the British and who had come from under treatment in British hospitals. Without seeing it, one can not imagine the joy shown by these men when they found that they were in an American Hospital with American doctors, nurses, and hospital corps men. Their usual expression was that "it seemed like home," and they did not try to conceal their pleasure. No complaint or criticism of the care

or treatment given them during their stay in the British hospital was ever made by any of these men, but "It is good to see American faces and have Americans taking care of us," was a commonly heard expression.

Fawkham, a small station, four and one-half miles from the hospital, was our receiving point and the sick and wounded fighting in Northern France came from Boulogne and Calais to Dover and then to us. Our first convoy of patients were Southerners; later we received many soldiers from the 27th Division, New York City's and State's own troops. Our officers had the novel experience of having in the hospital some of their pre-war civilian patients and our enlisted personnel met many of their former chums. This made conditions very personal and interesting.

As soon as a patient was able to return to active duty, he was sent to the American Camp at Winchester and then returned to his organization. All other cases appeared before a Disability Board, composed of three doctors, before discharge from the hospital was granted. Those cases fit for active duty in less than six months' time were graded "Class B" and remained in the hospital for treatment. Those who were well, but not useful in their original line of duty, were graded "Class C" and recommended for some lighter work than their former line of duty. This class of men were frequently assigned to some duty at the hospital. Those cases which could not recover within six months' time or were no longer needed in the American Expeditionary Forces were graded "Class D" and returned to the United States for treatment. The Disability Board passed on about 3500 cases between September, 1918, and the middle of January, 1919, when the last patients were ready for evacuation.

The entertainment of these soldiers was an important feature of the hospital life and for their contentment and peace of mind was as necessary as clothing and shelter. We had a recreation hall on the grounds with a seating capacity of 800 and this would be crowded with patients in wheel-chairs, on crutches, men with their arms in slings, and other convalescents whenever any entertainment was being given. Under the direction of our Commanding Officer, Lieut. Colonel Edwin H. Fiske, the various associations organized in the United States most capably cared for these patients and enough credit cannot be given to these enthusiastic and self-sacrificing men and women who did so much to cheer our soldiers abroad. Concerts, lectures, moving pictures, vaudeville entertainments and other amusements were frequently given, not only by our own American actresses and actors, but also by the British. The people of the neighborhood showed their good will and appreciation of the spirit of the Americans by organizing groups who visited the hospital on different days and thus helped to shorten the long hours of the sick. We were delighted one morning when a telephone message from Buckingham Palace came about 11:45 informing us that the King, the Queen, and the Princess Mary would visit our hospital that afternoon. It was later explained that notice of the visit was not given earlier in order not to disturb the routine of the hospital. The party spent the afternoon inspecting the wards and talking with the wounded. As a large number of our patients had been fighting in conjunction with the British, the King would converse freely with the men about the battles in which they were wounded. Ours was the only American hospital visited by the Royal Family in England. We encouraged the presence of visitors in order that the patients might benefit by their words of cheer and encouragement. Because of the proximity of our hospital to London, our patients saw and received many greetings from visitors from this side of the Atlantic. Each visitor brought messages of good cheer.

The religious life of the men was looked after and services were held by all beliefs in the little chapel which was among the hospital buildings.

An additional hospital of 1500 beds was started by our government outside the hospital grounds after our arrival in Dartford and three of the wards had been completed when the armistice was signed. All new construction stopped at this time.

We treated only Americans at the hospital. Our first patients were received on July 29, 1918, and the last patient was discharged January 21, 1919. During that time we admitted approximately 4500 men to the hospital; 60 per cent. of these were surgical cases and the remaining forty per cent. were medical cases. More than 1000 soldiers were returned directly to their organizations and about 3500 appeared before the Disability Board—a number of these were also returned to duty. Forty-seven of the patients died—25 of whom were among troops arriving from the United States with the most virulent form of influenza and its complications. Of this number 21 died of pneumonia and four of epidemic cerebrospinal meningitis.

The first patient who died in the hospital was a typical case of Addison's disease, without the bronzing. Autopsy showed a small focus of tuberculosis in the right upper lobe and both suprarenal glands were extensively involved. Many of the wounded were received with their first dressing still on. We had only one case of tetanus; this man died. There were eight cases of cerebrospinal meningitis with three recoveries. Two of these cases were among our female nursing staff and the third was a case of "flu" on whom a lateral ventricle puncture was done. All of our cases who died were autopsied and the findings were always most instructive. A detailed description of the treatment of surgical cases will probably be published before long.

Among our medical cases were found many interesting conditions, and we feel that the medical men profited more by their work than the surgeons did. Several of the Southern troops were admitted with a history of the symptoms of appendicitis with frequent attacks. Examinations of the blood in these cases showed a leucocyte count between 6,000 and 7,000 with an eosinophilia of from 7 to 12 per cent. The stools of these men were examined and the ova of the hookworm found.

Our Neurological Service was a busy one. Twelve cases of dementia precox were admitted to our hospital and sent back to the United States. Many cases of nerve injury, with involvement in scar

tissue came into the hospital, were examined, the lesion noted, and the necessary treatment recommended. Because of the slow recovery of this type of case, recommendation for return to the United States was usually made. The majority of the cases, however, were the so-called "war neuroses," or cases diagnosed as "psychoneurosis, anxiety state." These men presented the usual symptoms so vividly described in articles on this subject. They all recovered. Among the officers this nervous breakdown was usually due to worry because of the many responsibilities. Among the men we found that those who developed this condition were of somewhat unstable, poor-quality nervous system. The treatment was assurance of no immediate danger, ignoring the condition before the patient, giving no sympathy, keeping his mind occupied with pleasant surroundings, and giving him light agreeable employment. Our neurological ward was more like a club house than a hospital ward.

We had an unusual experience with a ship load of troops, coming from America, which arrived in England the latter part of September suffering with a type of influenza and complications, epidemic at that time. About 11:00 P. M., September 24, 1918, one hundred and sixty of the severest "flu" cases I have ever seen arrived from Southampton after a seven-hour car ride. All of these patients on admission showed cough, sneezing, profuse mucopurulent sputum, severe headache, pains through the body, pain and constriction through the chest, together with extreme weakness. In about 25 per cent. of these cases there was epistaxis either on admission or within the first twenty-four hours. In 30 per cent. of the cases there was bloody expectoration. Cyanosis was marked in many of the patients, with extreme difficulty in breathing. Among this convoy of 160 cases were found: 54 cases of pneumonia, and 5 cases of epidemic cerebrospinal meningitis. Twenty-five of the patients died: 20 of pneumonia, 1 of pneumonia with pneumonococcus meningitis, and 4 of epidemic cerebrospinal meningitis.

There also appeared among these patients: 14 cases of otitis media, 2 cases of scarlet fever, in 1 of which developed a case of bronchopneumonia with recovery; 1 case of measles; 1 case of mumps; 1 case of cervical adenitis which required operation; 3 cases of empyema; 1 case of erysipelas.

In the uncomplicated cases of influenza, the temperature was rarely over 102°, and the symptoms subsided within three or four days, leaving a severe cough with profuse mucopurulent expectoration which was easily raised. The pneumonia cases were both lobar and broncho in type. Those dying in the first three days showed complete consolidation of practically the entire lung. The organism found in the consolidated tissue was the pneumonococcus. Those cases not dying within the first few days showed more of a bronchopneumonia of a streptococcic origin. The findings at autopsy showed a marked difference between the lungs of those dying in the first seventy-two hours and those who died later. Those patients showing a lobar pneumonia returned to normal by crisis; those showing a bronchopneumonia returned to normal by lysis.

These patients arrived at the hospital after the symptoms were well developed, and it was difficult to obtain from the men a satisfactory history of the disease. The majority claimed that the attack had started about two days previously with cough, pain, fever, and general weakness. The striking features of the uncomplicated cases were excessive cough, sneezing, profuse mucopurulent sputum, pains over the body, and extreme weakness, continuing after the other symptoms had subsided. The severe symptoms subsided in from three to four days leaving the patient extremely weak with persistent cough and expectoration.

The pneumonia in these cases was more severe than the usual type of either lobar or bronchopneumonia. The amount of involvement was unusually large, and in the majority of cases but little toxemia was shown with this involvement. The patients suffered much from air hunger. There was marked cyanosis with the heart apparently not affected by toxemia. In some cases the involvement extended so rapidly that physical findings varied in a few hours. Those men who died within the first seventy-two hours died of asphyxiation because of the great extent of lung involvement; those dying after the first seventy-two hours died of toxemia due to influenza, pneumonococcic and streptococcic infection.

It is of interest to note the extent of lung tissue involved and the time of death of each patient after admission to the hospital.

Cases dying in:

34 hours	Lobar	All lobes involved.
43 hours	Broncho	Four lobes involved.
46 hours	Lobar	All lobes involved.
47 hours	Lobar	All lobes involved.
58 hours	Broncho	All lobes involved.
82 hours	Lobar and broncho	All lobes involved.
86 hours	Broncho	All lobes involved.
5th day	Lobar	Four lobes involved.
5th day	Lobar	All lobes involved.
6th day	Lobar	Three lobes involved.
6th day	Lobar and broncho	Four lobes involved.
6th day	Lobar	All lobes involved.
6th day	Lobar and broncho	All lobes involved.
8th day	Lobar	All lobes involved.
8th day	Broncho	All lobes involved.
8th day	Broncho	All lobes involved.
9th day	Broncho	All lobes involved.
9th day	Broncho	Four lobes involved.
9th day	Broncho (Meningitis)	One lobe involved.
10th day	Meningitis	No lobes involved.
11th day	Meningitis	No involvement.
11th day	Meningitis	No involvement.
12th day	Broncho	All lobes involved.

The examination of the blood showed various findings in the white cell count: there were some cases of leucopenia and some of leucocytosis. The findings in a number of cases that died showed leucopenia. The urine showed traces of albumin, few casts and no blood. A number of these patients showed the development of a loud systolic murmur at the apex of the heart, which disappeared eventually.

When these patients arrived, at eleven o'clock at night, we did not have masks ready for use. Nor did we have gowns, because this was the first sign of the "flu" epidemic we had and we were not prepared for it. Among our own men who attended this convoy upon its arrival, 15 developed symptoms of the "flu" and were in the hospital. Among the nurses who attended these patients, five were in the hospital with "flu," two with pneumonia, and

Report of Influenza Epidemic.

U. S. A. Base Hospital No. 37, Dartford, Kent, England.

Case No.	Pneumonia.			Involvement.	Complication.	Bacteriology.	Other Post Mortem Findings.
	Lobar.	Broncho.	Both.				
1	Yes	.....	.	Right and left lower lobes complete. In all other lobes large areas.	None.	*Staphylococcus pyogenes aureus*, pneumococcus.	Edema and congestion of lungs, Fatty infiltration of liver.
2	.	Yes	...	All lobes involved to a marked degree.	None.	Streptococcus, pneumococcus.	Serous effusion in pleural cavities, edema and congestion of lungs, fatty infiltration of liver.
3	Yes	.....	..	Right and left lower lobes complete. Large portions of both upper lobes. Lower half of middle lobe.	None.	No culture taken.	Serous effusion left pleural cavity, edema and congestion of lungs, fatty infiltration of liver, acute parenchymatous nephritis.
4	Yes	..	....	Right and left lower lobes complete. Large portions of both upper lobes.	None.	No culture taken.	Edema and congestion of lungs, serous effusion in pleural cavity.
5		Yes	...	All lobes involved markedly.	None.	*Staphylococcus pyogenes aureus*, pneumococcus	Serous effusion in pleural cavity, subpleural hemorrhages in both sides, fatty infiltration liver. Congestion other organs.
6		.	Yes	Lobar: Right lower lobe. Broncho: Right upper and middle left upper and lower.	None.	Influenza bacillus, pneumococcus.	Atypical left lung, middle lobe presents showing bronchopneumonia, fatty infiltration liver.
7	.	Yes	.	Entire left lung except small apical portion. Entire right except small portion at base. Areas of middle.	Acute fibrinopurulent meningitis, pneumococcic.	Lung culture: Pneumococcus. Spinal fluid smear and culture also yield pneumococcus.	Acute fibrinous pleurisy, early septic spleen, fatty infiltration liver.
8	Yes	.	.	Entire left lower. Lower half of left upper. Entire right lung except apex of upper, and upper border of lower.	Abscess of the lung.	Influenza bacillus.	Early septic spleen, chronic fibrinous pleurisy.
9	Yes	. .	.	Entire right lung. Few small areas in left.	Empyema, right pleural cavity.	Pneumococcus.	Early septic spleen, chronic fibrinous pleurisy.
10	Yes	.	.	Entire right lung except small portion at apex. Few patches in left lung.	None.	Influenza bacillus, pneumococcus.	Acute fibrinous pleurisy, serous effusion in right chest, fatty infiltration liver.
11	.	...	Yes	Entire upper and lower left except small portion at lower border of each. Diffuse broncho: Right middle lobe throughout.	None.	Pneumococcus.	Edema and congestion of lungs, chronic fibrinous pleurisy.
12	Yes	.	.	Entire left except small portion at the apex and lower border of lower lobe. Entire right except lower margin.	None.	Pneumococcus.	Acute and chronic pleurisy, congestion of spleen, retention cyst of left kidney.
13	.	..	Yes	Left: Entire, and area in lower right. Marked broncho throughout. Small patch in middle.	None.	No culture taken.	Chronic fibrinous pleurisy, edema and congestion of lungs, congestion of spleen and kidneys.
14	Yes	..	..	Left: Entire lung except lower border of lower lobe. Right: entire lung except anterior half of upper lobe and middle lobe.	None.	No culture taken.	Acute fibrinous pleurisy, early septic spleen, fatty infiltration of liver.
15	...	Yes	. .	Left: All lower and lower half of upper. Right, lower lobe and patches through upper and middle.	None.	Influenza bacillus, streptococcus	Acute fibrinous pleurisy, early septic spleen.
16	.	Yes	.	Diffuse throughout all lobes or both sides, most marked in lower lobe, right lung.	None.	Influenza bacillus, streptococcus.	Acute fibrinous pleurisy, bilateral hemorrhages in adrenals.
17	...	Yes	..	Nodules all through lobes, left side, upper and lower lobes right side.	None.	Streptococcus.	Acute fibrinous pleurisy, hemorrhage in myocardium, septic spleen.
18	. .	Yes	.	Entire left lung except apex Upper and lower right. Few nodules in middle lobe.	None.	Pneumococcus. *Staphylococcus pyogenes aureus.*	Acute fibrinous pleurisy, septic spleen.
19	..	Yes	. .	Both lower lobes and upper on left, and upper on right side.	Empyema, right thorax.	Pneumococcus, streptococcus.	Abscess lower right side, septic spleen, acute fibrinous pleurisy.
20	..	Yes	.	Both lobes left side, entire right side except small area at apex	Pleurisy.	Streptococcus.	Acute chronic pleurisy, chronic fibrinous pericarditis, septic spleen.
21	.	Yes	..	Few nodules right lower lobe.	Epidemic cerebro-spinal meningitis.	Meningococcus.	Septic spleen.
22	..	.. .	...	Lungs clear.	Epidemic cerebro-spinal meningitis.	Meningococcus.	Septic spleen.
23	.	.....	....	Lungs clear.	Epidemic cerebro-spinal meningitis.	Meningococcus.	Small amount of hypostatic congestion.
24	..	.. ..	....	Lungs clear.	Cerebro-spinal meningitis epidemic.	Meningococcus.	Small amount of hypostatic congestion.
25	.	Yes	....	Entire right lung, entire left lung.	Acute fibrinous pleurisy.	Pneumococcus.	Acute fibrinous pleurisy, septic spleen, chronic parenchymatous nephritis, multiple infarcts right kidney.

two with epidemic cerebrospinal meningitis. All these cases recovered.

Early during the morning after the arrival of the convoy, the following orders were issued to prevent the spread of the disease through the hospital:

"U. S. A. Base Hospital No. 37, American Expeditionary Forces. Date, September 25, 1918.

"A number of patients have been received at this hospital suffering from a

"COMMUNICABLE DISEASE.....INFLUENZA.

"Every precaution must be taken to prevent the spread of this disease through the hospital.

"These patients must and will be isolated until the danger to others is passed.

"They will have a distinctive mark upon their clothing during the infective period.

"All doctors, nurses, male or female, and any other person coming in contact must wear masks and gowns and be instructed in the care of their hands and clothing. They must place some substance, such as a nasal cream of camphor-menthol and vaseline or lanoline, in each nostril at least twice

during the twelve hours' contact, and before retiring wash the mouth and nostrils with some alkaline cleansing and antiseptic solution.

"Each patient must be taught the proper use of a handkerchief or a piece of gauze to prevent the spread of the disease when coughing or sneezing.

"All wards must be divided into cubicles.

"All patients must be carefully screened and segregated."

The enforcement of this order had much to do with the prevention of the epidemic in the hospital. We made a quarantine area of the buildings in which these patients were being cared for, and really had a contagious disease hospital within our own hospital. There was no outbreak of the disease among the 1700 patients in the hospital at that time. As a result of our care when the epidemic was raging in England, there was less "flu" in our 170 acres than anywhere else in England. We encouraged our own men not to visit outside the hospital grounds.

The chart shows the findings at autopsy of those cases which died. These autopsies were performed by Capt. Beecroft, Chief of our Laboratory Section.

Our disappointment at not serving in France entirely disappeared when we found the amount and character of the work we could do in England. We received our cases earlier than the Base Hospitals in France. We were not used as an Evacuation Hospital but as a Base Hospital. The care of the patients was more thorough and satisfactory and we were able to follow the cases to recovery.

The success of the hospital would have been impossible without the cooperation and encouragement of Brig. General F. A. Winter, Chief Surgeon of the American Troops in England, and his capable assistants who did everything in their power for the establishment of the hospital and for the comfort of the troops.

During our life in the army we met many able, large-minded, energetic, and capable men who had given up the possibilities of lucrative practices to serve with the army. They are all deeply interested in improving the condition of the service. They deserve, are entitled to, and should receive, the support and cooperation of the Medical Profession at large in improving the Medical Corps and in making it the strongest branch of the army. Before the present war but few of us knew anything about the medical conditions in the army—now we know that with our backing and support much that was formerly lacking can be secured and improvement must result. I know that these doctors look to us hopefully for advice, support, and cooperation.

108 Prospect Park West.

Retention of Chlorides in Uremic Eclampsia.—Holst has analyzed the blood of nine subjects from this viewpoint. The condition was one of nephritis with chlorine retention, known as chloruremia. He finds that the relationship between the serum content and clinical uremia is not exact as in azotemia. Increased concentration in the serum of the chlorides is of much less significance. There is considerable evidence that the symptoms of chloruremia are due to a retention of chlorides without reference to increased concentration, the chief consequence being the visceral edema.—*Norsk Magazin for Lacgevidenskaben.*

GONOCOCCUS PNEUMONIA:

REPORT OF A PROBABLE CASE.

By MARTIN ROSS, M.D.,

NEW YORK.

THE frequency of gonococcus infections, and the undisputed fact that septicemia with metastases is not uncommon, would make it reasonable to suppose that lung infections of this origin must occasionally occur. Yet, after an exhaustive search of the literature, reference has been found to but one case of gonococcus pneumonia. This case, reported by Von der Bressel,* although inconclusive, bears a resemblance to the present one. His case is that of a man aged 32, who came under his care for an acute gonorrhea. In a few days the patient complained of severe headache, signs of lobar pneumonia quickly following. Late in the course of the disease, he developed a cough, with sputum scanty, tenacious, milky white, and bloodless. Pure cultures of gram negative diplococci were obtained from the blood and sputum. In a week the temperature began to fall by lysis, complete resolution resulting by the eighteenth day.

Case Report.—Our patient (A. C.) was a female, age 16 years, of Italian parentage. She first came under the writer's observation, at the infirmary of the Randall's Island Hospital, in March, 1918, at which time she was suffering from a severe form of dysmenorrhea, a condition existent for a number of years. At this time her symptoms subsided, and she was discharged a few days after admission.

Family History: Father died at the age of fifty-two, with the diagnosis of nephritis. Mother and seven children are alive and well. No history of disease, hereditary or otherwise, in the family.

Previous History: As a child patient had measles and scarlet fever. She started school at five years, and had only reached the grade of 4B at thirteen, at which time she left school. Repeatedly failed to be promoted. At the age of twelve, she had acute rheumatic fever, and was confined to bed for three months. After leaving school, the patient became rather ungovernable, and there was a definite history of sexual irregularities and a chronic vaginal discharge.

She was committed to the institution March 1, 1918, for moral delinquency. Psychological tests gave her a mental age of six years four months, by the Terman scale, with an intelligence quotient of .46. Wassermann negative. Upon entrance into the hospital, routine examination having revealed the gonorrheal nature of her discharge, the patient was accordingly transferred to the female genitourinary division, where she was treated intensively for her infection. As a consequence, an acute exacerbation resulted, with a profuse vaginal discharge, and accompanied by a return of her menstrual difficulties. For this reason, she was transferred to the author's service, where she was again seen April 10, 1918.

Present Illness: Upon admission to the infirmary, patient complained only of a very severe headache. Her face was flushed, temp. 103.4°, pulse 98 full and regular, resp. 24. Menstrual flow beginning. The vaginal smear taken on the 10th was reported positive for gonococcus, and hence she was placed upon strict gonococcus precautions.

April 14: Patient persistently lies upon her right side and complains of severe pain in the right chest, exaggerated by deep inspiration. Face markedly flushed, with slight circumoral pallor. Large crop of herpes on both lips. No cough, but respirations are rapid with dilatation of alae nasi. Temp. 104°, Resp. 46, Pulse 136. Physical examination of chest shows dulness over the lower and middle lobes of the right lung, with increased voice sounds and fremitus, and showers of crepitant rales at the end of inspiration.

*Von der Bressel *Muenchener medizinische Wochenschrift*, March 1903.

Diagnosis made of lobar pneumonia. Blood taken for culture.

April 15: No additional complaints. Pulse weak and irregular, rate 100; Temp. 104°, Resp. 36. Patient has no desire for food, but takes water freely. Blood count gives the following: Erythrocytes 4,500,000; leucocytes 22,000, with a differential count of 92 per cent. Urine reported as being alkaline, specific gravity of 1015, and showing the presence of albumin, glucose, a few hyaline casts, pus, red blood and epithelial cells. Blood again taken for cultural purposes.

April 16: Lower and middle lobes of the right lung completely consolidated. Patient says she feels well. No cough or expectoration. Report of the blood culture of the 15th showed a pure culture of gram negative diplococci.

April 18: Patient very restless with respirations labored, rate 50. Temperature and pulse remain high. There is now a slight cough at frequent intervals, with scanty expectoration. The sputum is milky white, extremely tenacious, and contains no blood. Smear and culture of sputum taken. Physical examination of the right chest revealed no change. In the upper lobe of the left lung there is slight dulness with numerous crepitant rales. Report of the blood culture taken on the 15th shows a positive growth of Gram negative diplococci.

April 19: Patient very restless throughout the entire day and considerably disturbed by severe cough. Sputum is still scanty, tenacious and milky white, and contains no blood. Report of the sputum smear taken on the 18th shows great numbers of gram negative intracellular diplococci, and also a few gram positive organisms.

April 20: At 1 P.M. patient's condition became worse; pulse weak and thready; respirations very labored, and 54 per minute. Extreme degree of cyanosis and venous congestion, with markedly dilated heart. Phlebotomy was performed with the withdrawal of 250 c.c. of blood, and resulted in immediate improvement. Oxygen administered.

April 22: Examination this day showed dulness over the lower and middle lobes of the right lung, with numerous moist rales over this area. Upper lobe of the left lung completely consolidated. Protracted cough, but scanty sputum. Patient upon oxygen since the 20th. Blood culture taken.

April 24: Severe grade of cyanosis. Respirations labored. Systolic blood pressure 160, diastolic 85. Marked venous engorgement. Bubbling rales and dulness at both bases indicative of beginning pulmonary edema. Phlebotomy performed with the withdrawal of 200 c.c. of blood. Sputum and blood cultures of the 22nd both showed pure growths of gram negative diplococci, with a tendency toward tetrad formation. Vaginal smear revealed gram negative intracellular diplococcus, although active discharge had ceased.

April 26: Respirations this P.M. became very superficial, rate 50. Pulse 136, Temp. 102.6°. Signs of pulmonary edema present at both bases.

April 27: Another blood culture taken this day again produced a pure growth of gram negative biscuit-shaped diplococci. Clinically the case is progressively worse. Patient again menstruating.

April 28: No change in condition. Menstruation ceased.

April 29: At the right base posteriorly there is marked dulness, with breathing somewhat amphoric in type. Numerous moist rales of a definite metallic quality add to the likelihood of pyopneumothorax. Expectoration is less tenacious and more abundant. This with an extremely offensive odor to her breath are indicative of pulmonary abscess or abscesses. Lung puncture performed. Needle inserted into the left chest at the level of the seventh rib, posterior axillary line. Five c.c. of a sterile bouillon broth were injected into the lung, the needle remaining in situ. At the end of one minute 2½ c.c. of the blood-tinged broth were aspirated and cultured. A few small abscesses on nose and ears noted. Cultures from these yielded on overwhelming growth of staphylococcus. Clinically patient is very much worse. Respirations are very rapid and labored, and the pulse is weak. She complains of generalized pains, which are, however, most marked in the right arm and back. There are no embolic or joint symptoms. No nervous or mental involvement. Heart sounds show no valvular lesion.

April 30: Patient has been sweating profusely. Breath has a distinctly fetid odor. Sputum culture of this date again shows gram negative diplococci in pure growth. White blood cells 14,000, with a differential of 82 per cent. Red cells number 3,500,000.

May 1: At 4 A.M. patient began to fail rapidly; respirations very shallow and pulse imperceptible; cyanosis extreme. At 4.30 A.M. she was reported dead. At 8 A.M. a needle, under sterile conditions, was thrust (post mortem) into the right chest with the withdrawal of a few c.c. of bloody fluid. Aspiration of the left chest produced a milky purulent fluid. The smears from both these specimens showed great numbers of gram negative diplococci, and a few gram positive cocci. Cultures proved to be contaminated. The report of the lung puncture (ante mortem) performed on the 29th of April, stated the presence of a pure culture of Gram negative diplococci.

Post mortem examination performed May 1 revealed the following: Both lungs were riddled with minute abscesses. Consolidation of the upper left lobe. In the lower lobe of the right lung was a large abscess containing about 400 c.c. of light-green pus. The right upper lobe showed a walnut-sized abscess cavity, with blackish green indurated walls. Fibrinous pleurisy of right side with dense adhesions.

Left kidney hydronephrotic, the left pelvis and ureter dilated, containing 50 c.c. of clear urine. The remaining viscera, aside from the intense congestion, were normal. Microscopically, sections of the lungs showed multiple minute alveolar abscesses, with great numbers of gram negative diplococci, and a few gram positive cocci.

Résumé.—The organism obtained from the blood, the sputum, and direct stab of the lung, was in each case a gram negative diplococcus in pure culture, while the patient was known to have an acute exacerbation of a chronic gonorrhea. It grew very sparsely, or not at all, on all simple media but with greater ease on those to which human serum had been added. Neutral preparations of meat-infusion broth or agar, with serum in the proportion of 3 to 1, were used. It was very sensitive to heat, but resisted the temperature of the ice box for two to three weeks before necessitating transplantation. Macroscopically the colonies appeared as delicate grayish growths with a pale suggestion of yellow, a definite wavy margin, and a slimy consistency. The only other organisms to be considered here are the *Diplococci catarrhalis* and *meningitidis.* The *Micrococcus catarrhalis* which is morphologically indistinguishable from the gonococcus, seldom gives rise to more than catarrhal inflammations, and is easily differentiated from the gonococcus in showing none of the fastidious cultural requirements of the latter. To differentiate the meningococcus from the gonococcus is more difficult, and, in the absence of agglutination tests, not conclusively demonstrable. However, complete lack of all nervous involvement, the greater difficulty of its cultivation, meningococcus growing more readily on all meat-infusing media, even in the absence of serum or ascitic fluid, its greater resistance to low temperatures, meningococcus dying out within a few days if placed in the ice box, all point toward the gonococcus as the causative agent.

As to the mode of entrance into the circulation not much can be said. Gonococcus septicemia often occurs following specific urethritis, with no other focus of infection. In this instance, the explanation may lie in the presence of a dysmenorrhea, in so much as, with the damming up of her menstrual

flow, and the existence of numerous atria of infection, the organisms might readily have been swept directly into the blood current.

Conclusions.—1. The patient admitted with an acute exacerbation of an old gonorrheal infection, superimposed upon a dysmenorrhea.

2. Lobar pneumonia following an atypical course.

3. Sputum scanty, very tenacious, milky white, with no trace of blood at any time.

4. Pure cultures of gram negative biscuit-shaped diplococci were obtained from the sputum, the blood and lung puncture.

5. Termination of the lung process in pulmonary abscesses.

1963 Seventh Avenue.

THE NEED OF CO-OPERATION BETWEEN THE MEDICAL AND DENTAL PROFESSIONS.

By S. HERDER, D.D.S.

MOUNT VERNON, N. Y.

It has been well said, that when a dentist treats a tooth, he should not only see that particular tooth, but the entire individual of which it is a part. In other words, in treating a tooth, he should take into consideration, whether normal or abnormal, the physical condition of the entire human body of which that tooth is an integral part. How can he do this unless he has a tolerably good understanding of the great number of diseases to which human beings are heir? That indeed, is the great pivotal question.

It is just exactly at this point where the great tragedy of present-day dentistry comes in. That diseases of the body very frequently have a deleterious effect upon the teeth, and that diseases of the teeth also have a similar effect upon the body are now clearly established, authoritative facts. Somewhat as follows do these facts make their mute, pathetic plea: "For the sake of human health, fellow dentists and physicians, do your utmost to get at least a tolerably good understanding of the inter-relation between diseases of the mouth and body!"

Simply because a great majority of dentists and physicians do not possess this much needed understanding, are they, therefore, justified in coolly and indifferently ignoring this heart-rending plea, with the assertion that they do not care or do not want to know these things?

Practising dentists and physicians should not only strive most energetically to obtain this much needed information, but they should give their patients the benefit of what little information they already possess upon this vital subject. "Co-operation between dentists and physicians" has been and must continue to be the sharp, shrill, impressive cry of the leading men of the medical and dental professions.

Almost at every turn this cry keeps ringing in our ears. In practically every phase of dentistry, whether it be pyorrhea, orthodontia, oral surgery, diagnosis, artificial dentures, or any other phase of dentistry, cooperation with the physician has very often been found to have been of inestimable value.

On the other hand, it has been conclusively shown that patients suffering from certain types of rheumatism, neuralgia, ulcers of the stomach and other organs of the body, insanity, and many other diseases and lesions of the human body, have regained their normal health after having their teeth and mouth properly treated.

In referring to asthma, Dr. Mark I. Knapp of New York said quite recently, in substance, that poor teeth or lack of sufficient teeth for the proper mastication of food may be definitely considered as a cause of asthma.

Dr. V. E. Mitchell, in discussing the subject of cleft palates before the Northern District Dental Society of New York last December, pointed out quite forcibly that a great many cleft palate cases have been operated upon surgically with most unsatisfactory results, when consultation with a dentist would have proven that very favorable results could have been obtained by the insertion of a proper dental appliance.

Dr. E. C. Rosenow of Minnesota, in his lecture before the First District Dental Society last March, said in substance, that the diseased condition of the teeth and their adjoining tissues has very often been shown to have been the direct cause of the extraoral diseases and lesions of certain types of patients. His concluding remarks consisted in advocating very strongly the great need of close cooperation between the medical and dental professions.

In the face of such facts as the above, one is often appreciably chagrined to learn of the great amount of ignorance upon these important matters that is shown by many physicians. For example, when treating certain types of disease, and suspecting that the teeth may be the seat of the trouble, some physicians have sent their patients to a radiographer to have their teeth radiographed. The radiographer being limited strictly to radiography, knows nothing about the clinical history of those teeth. The physicians having no dental training, are of course in no position to determine except in a general way, what the condition of those teeth are, whether normal or abnormal. Have those physicians a right, therefore, to formulate conclusions and opinions involving their patients' health, upon such meager and flimsy evidence?

Of course what these physicians should have done, when they suspected the teeth as a cause of their patient's ailments, was to send them to a dentist. By cooperating with the dentist rather than with the radiographer, a real intelligent understanding of the patient's teeth would have been obtained, if such an understanding was ever expected to be obtained.

The purpose of the joint medical-dental meeting held in Washington Irving High School, New York City, March 4, 1919, was to find ways and means of actually realizing, as early as possible, a closer cooperation between the medical and dental professions.

The idea brought out that the dentist ought to have a medical education, or that the physician should possess a dental education, does not enter into the question at all. In no conceivable way, does this idea prevent the physician from enlightening the dentist upon diseases of the body as it bears upon diseases of the mouth; nor does it bar the dentist from enlightening the physician

upon the diseased condition of the mouth and its possible effects upon out-of-the-mouth diseases.

Simply because we cannot learn, perhaps as much as we ought to upon this important subject, is there any just and honorable reason therefore, for concluding that we should not learn anything at all about it?

The upshot of the foregoing remarks is that the dentists and physicians should not wait until some vague future time, but should *act right now*, in this extremely vital matter of securing educational cooperation between them.

An excellent means of interchanging educational ideas between the two professions is the following: Let the dentists be invited by medical societies to medical meetings at which such subjects, as the important bearing of out-of-the-mouth diseases upon diseases of the mouth are being discussed. At these meetings the dentists should not only listen, but take an active part in the discussion. Similarly, by way of reciprocity, or irrespective of any invitations on the part of the medical societies, the dental societies ought to make it their business, to invite the physicians to dental meetings at which such subjects as the important relation of mouth diseases to out-of-the-mouth diseases is being discussed.

Here also, the physicians should not only listen but actively participate in the discussion. The publication of such discussions, in addition to other articles along similar lines, in the medical and dental journals of the country, would still further aid in obtaining a closer cooperation between both professions.

A determined effort to get the physicians and dentists together, for the purpose stated above, was made for the first time within my knowledge, on March 4 last, under the auspices of the Allied Dental Council of New York. It ought to be the forerunner for many others, to follow at an early date, wherever dentistry and medicine are being practised.

As Drs. M. I. Schamberg, Robert T. Morris, S. Danna Hubbard, Medical Inspector of the Department of Health of New York City, and others showed at the above mentioned meeting; and as Drs. R. Ottolingui, M. L. Rhein, H. Biggs, Health Commissioner of New York State, and many others have stated in the substance of their communications, the need of cooperation between these medical and dental professions is of vital importance.

In conclusion I wish to make the following indisputable and extremely pertinent statement: Physicians and dentists can never hope to give their patients the best that their respective professions offer, if they persistently and carelessly refuse to take advantage of the much needed cooperation between these two professions. Let us take advantage of each other's experience, fellow dentists and physicians, in the way suggested above. We shall thus materially assist in cementing together invaluable bonds of fellowship between the members of both professions. The inevitable result will be the conferring of a distinct benefit not only upon ourselves, but upon all mankind as well.

6 East First Street.

Medical and Surgical Lessons of the War.

IMMEDIATE ACTIVE MOBILIZATION IN THE TREATMENT OF GUNSHOT WOUNDS OF JOINTS.

By Lieut.-Col. CHARLES WILLEMS.

BRUGES, BELGIUM.

SURGEON-IN-CHIEF OF THE BELGIAN MILITARY HOSPITAL OF THE FRONT AT HOOGSTADE; PROFESSOR OF CLINICAL SURGERY AT THE UNIVERSITY OF LIÈGE.

No surgical rule is more firmly established or has been more universally followed than that which demands immobilization in all joint lesions, from the most insignificant to the most serious. At the same time the disadvantages of immobilization have been fully appreciated, for every one knows how rapidly the functions of the joint and of the muscles connected with it are thereby compromised. Immobilization of a joint for only a few days is always followed by more or less stiffness and muscular atrophy. It is well recognized also that these troubles, once established, are very persistent and often do not completely yield to massage, mechanotherapy, electricity, hot air, and other physiotherapeutic measures. Even in the most favorable cases these measures must be applied for weeks and months before bringing about any marked results.

If then, in spite of these serious disadvantages, the practice of immobilization has been continued for so long a time, it has been because it is regarded as indispensable—a necessary evil. It is regarded as the only means of easing the pain, of preventing an "aggravation of the lesions," of preventing "irritation" or "inflammation." And, indeed, it is frequently observed that the pain is increased and that very serious results do sometimes follow imperfect immobilization, and that all these troubles subside again as soon as absolute immobilization is obtained.

And with even more reason, apparently, the greatest care is taken to keep the joint absolutely immovable in case of suppurative arthritis in order to avoid a "scattering of the germs" and an extension of the infection to the still healthy parts of the synovia and to the periarticular tissues, not to mention the sedative effect of immobilization upon the severe pains of suppurative arthritis, an effect shown by the patient's apprehension of the slightest movement. In all these conditions immobilization has always been regarded as of such capital necessity as to justify the production of all the sequelæ which followed in its train.

It is to be noted, however, that a certain reaction against prolonged immobilization has manifested itself in recent years. It was especially under the influence of the writings of Lucas-Championnière relating to the treatment of certain fractures without immobilization by means of massage, that articular lesions—non-infected ones, be it understood—benefited by a shortening of the period of immobilization, and that surgeons had acquired the habit of saying, with significant unanimity, that an injured joint should be mobilized "as soon as possible." This formula is indeed a little vague, but it nevertheless indicates a modicum of progress.

I myself had been struck, in the surgery of industrial accidents, by the mediocre results of the classical treatment in case of traumatic effusion of the knee. One began usually by immobilization and compression and ended with all the forms of physiotherapy which is but too often invoked to repair the results of error or shortcomings of the surgeon. The results were far from brilliant. Even a simple hemarthrosis did not always get well with complete functional restoration, or did so only after weeks and months of treatment.

The works of Rochard and of Thooris had certainly improved matters a little in replacing immobilization by progressive resistive movements, but I assured myself that the true cause of functional impairment in cases of traumatic joint effusion was to be found in the distention of the synovia and that it would undoubtedly suffice to evacuate this effusion by puncture in order to bring about a *restitutio ad integrum*. From my very first case I felt that I was on the right track. As soon as the fluid was evacuated the function of the joint was immediately re-established. Not only did the joint movements cease to be painful, but even walking became possible. The injured man who could stand only with the greatest difficulty or who had been brought on a stretcher, found himself, to his great astonishment, relieved of his pain as if by magic and able to walk naturally, flexing the knee. Once he had thus begun he could go on indefinitely and could even continue to walk with impunity up to the point of fatigue as I counselled him to do. This immediate and complete use of the joint gave rise to no trouble; on the contrary, as one might *a priori* have foreseen, neither stiffness nor atrophy was experienced. The patients got well in a few days, even when slight return of the effusion called for a second puncture, which was exceptional. The cure was so perfect that when I saw the cases some months later some of the patients had forgotten which knee it was that had been tapped. In 1909 I was able to report to the German Surgical Congress some thirty cases of traumatic hemarthrosis or hydrarthrosis treated by this new method. All the patients had been cured in a few days, without the least mishap and with anatomical and functional integrity of the limb.

The method was widely adopted in Belgium and France, and I had knowledge of hundreds of cases in which, in the hands of surgeons treating industrial accidents, it had been followed by unvarying success without any untoward incident.

This initial success naturally led me to have recourse to the same method in the case of articular lesions more important than simple hemarthrosis. I used it in case of joint wounds by cutting instruments, and there also the results were excellent. Then in fractures of the patella, treated by *cerclage*, making the patient walk five or six days after the operation, and again the experience was conclusive. Walking was at first with the knee held stiff, but in a few days articular movement began to return and in less than a month walking was almost normal.

I was at this point when the war began. Since then the great frequency and infinite variety of joint injuries that came under observation in my service at the military hospital at the Belgian front at Hoogstade have enabled me to progress much further along the way of mobilization in case of injury to the larger articulations. In proceeding by steps and passing from the more simple to the more serious injuries, I mobilized immediately, first penetrating wounds with destruction of the soft parts but without osseous lesions, then wounds with projectiles in the joint, then all kinds of intra-articular fractures. I did not limit myself to fresh, non-infected wounds, but also treated purulent arthritis after the same manner, and it was especially in this so grave complication that the method gave the most astonishing results.

Before describing the procedures employed in these various cases it will be necessary to lay down the general rules of the technique.

The essential principle of the method and the object one must seek to obtain is to re-establish immediately and completely the function of the wounded articulation. One will readily understand, however, that this end cannot always be attained with equal facility, and this for various reasons. All joints have not functions of the same complexity. If we limit our observation to the knee and the elbow, we note that the function of the elbow may be regarded as entirely restored when we have succeeded in re-establishing in full degree the movements of flexion, extension, and rotation. In the case of the knee, on the other hand, we cannot speak of perfect restoration of function until, in addition to complete flexion and extension, we have succeeded in enabling the patient to walk. In other words, in the case of the articulations of the upper extremity mobility comprises the entire function, while in the case of those of the lower extremity mobility constitutes only a part of the function, another part of which consists in walking, that is to say, the possibility of the joint supporting the weight of the body during movement. On this account it is a more simple matter to restore the function of the elbow than that of the knee.

On the other hand the importance and the extent of the lesions affect equally the facility with which we can obtain a return of function. It is easy to understand, for example, that in the case of the knee, extensive intraarticular fractures will not allow of this immediate and complete restoration of function, since they will not permit walking, while similar lesions of the elbow may be regarded as capable of immediate and complete functional restoration, since in the elbow we have to consider only mobility.

There are, however, certain general rules to be followed in the restoration of mobility, and these rules are the same whether we have to do with the elbow or the knee. It is to these two joints, which are the ones most often affected, that we shall confine our study.

These general rules, which are, moreover, very simple, may be summed up as *immediate active mobilization*. Simple as they are, however, they are nevertheless often lost sight of. Each day I see surgeons obtaining imperfect results because they have not followed strictly enough the rules of this mobilization. One must not be satisfied with a partial result. The method will give much better results to the one who knows well how to execute it.

Technique of Immediate Active Mobilization.—

The term "immediate active mobilization" should be taken in its literal sense. The mobilization should be *active*, that is to say, made by the wounded man himself and obtained by the contraction of the muscles which normally move the articulation. Among the physiological movements of each joint there are those which are essential and those which are accessory. It is on the former that we must insist at first; in the knee and the elbow these are extension and flexion. Active mobilization cannot at all be replaced by passive mobilization which has no effect upon either the musculature or the nutrition of the joint, but only tends to restore motion. It is also very bad to combine these two modes of mobilization, adding passive movements to the active movements in the hope of getting along more rapidly and increasing the extent of the movements. I have seen deplorable results from this practice, such as inflammatory exacerbations which restricted the extent of the movements and rupture of extra-articular foci of infection into the synovial sac.

The mobilization should also be *immediate*, that is to say, begun without any delay as soon as the patient comes out from the anesthesia. One must therefore not let him "rest" at first for several hours or several days, as one is inclined to do. It is of the greatest importance to begin the movements immediately after the operation, as soon as the patient regains his consciousness. The patient can be made to do them much better at this time than if they are begun later, and they will also be of greater extent at the very outset.

This immediate mobilization in the strict sense of the word has really nothing in common with the so-called early or precocious mobilization of which much is said at the present time, and which, although constituting an advance over long continued immobilization, can never give the astonishingly rapid result of immediate mobilization; neither can it prevent atrophy of the quadriceps which is so readily produced and which absolute immediate mobilization alone is capable of preventing.

In addition to being active and immediate the movements should also be pushed to the greatest possible extent. This extent will often not be very great for the first movements, but by urging the patient to greater efforts the amplitude of the movements will be increased rapidly and will soon attain the normal or nearly so. We must not content ourselves with a partial result, as I have said. The surgeon ought to know how to induce his patient to make the necessary effort not only to preserve the degree of mobility already obtained, but also to increase constantly the extent of the movements. If we leave this to the patient to do he will always recoil from the indispensable effort necessary to increase the extent of the movements and will content himself with always reproducing the same movement and to the same degree. Finally, the movements must always be executed without any respite. I am often asked how many times a day I have these movements repeated. I reply "incessantly;" it is an essential condition to obtain complete success that the joint should never, so to speak, be immobile. Undoubtedly the wounded man will become tired, moving his joint so without any rest, but this fatigue is of no particular account. Continuous effort is necessary because the more the movement is repeated the easier and more extensive it becomes. If, on the other hand, one lets the joint rest for a time it will be seen that at each renewal of the movements there is a certain stiffness and a certain diminution in amplitude. This fact is noted especially after the repose of the night, and the patients declare in the morning that their joints are "stiff" and they know that it will be necessary for them to make a long series of movements in order to get the joints supple again and to regain the degree of mobility of the previous evening.

The technique of my method may be summed up under the brief formula of active, immediate, maximum, and uninterrupted mobilization. This treatment calls for an effort which the patient will make with the necessary perseverance only if he is constantly urged thereto. These patients ought therefore never to be left to themselves; on the contrary they ought to be constantly watched by a personnel well acquainted with the treatment. I can never sufficiently impress upon surgeons who wish to obtain good results the necessity of detailing to these patients an orderly or a nurse who will never, so to speak, leave them, and will be constantly urging them to make frequent and extensive movements, encouraging and stimulating them always to renewed effort. The orderly or nurse must be especially instructed to urge the patient to make by preference that movement which he makes with the most difficulty, the most incompletely, and the least frequently. This movement in the knee or elbow is that of extension. This is a matter of the greatest importance. I see every day surgeons who obtain only imperfect results because they have not been strict enough in insisting upon this, and success depends more upon this well-conducted and well-directed treatment than upon the operation itself. If we do not take care we shall see muscular atrophy appear in cases in which mobility is well preserved. Thus I have seen marked atrophy of the quadriceps in patients in whom the mobility of the joint was fairly good but in whom complete extension of the knee had not been obtained from the earliest moment. In order to avoid this atrophy of the quadriceps one has often only a few hours at his disposal; and once the atrophy has begun, complete extension later will be in vain, for one then cannot prevent this atrophy persisting and even increasing.

Moreover, as I said before, the movements become more and more easy in proportion as they are repeated, but on the contrary the patient who neglects these movements is confronted with more and more difficulty in making them and he makes them more and more infrequently because he has become discouraged. One fact of which we must persuade ourselves is that active, immediate mobilization is always possible. It goes without saying that it will not always be of the same degree, since the extent of the osseous lesion and the amount of destruction of the joint ligaments must evidently be taken into account. But other conditions also influence the ease of these active movements. In the first place we have to note the courage and good will of the patient. One man who is intelligent and energetic will have a pride in doing what is asked of him. Another, with less courage and a feeble will, must be constantly spurred on or he will make only partial movements. It is easy to understand that the

first one will obtain a complete result much more rapidly than the second. But courage is not the only requisite. The skill of the wounded man in contracting the individual muscles necessary to produce a given movement also enters into the success of his treatment. Some of the wounded exhaust themselves in vain efforts to contract the quadriceps and so raise the leg above the bed. They contract all the muscles except the ones they should contract. Others, on the other hand, from the very first and without special effort, project the nervous influence directly to the muscle or muscular group which is concerned in the action. Here, again, the education of the patient must be under the direction of the nurse.

When I speak of moving the wounded joint my hearers never fail to ask if the movements are not painful. This is a very natural question from surgeons who are convinced that pain cannot be avoided except by immobilization. In reply to this question I am accustomed to have the interlocutor see the patient move his wounded joint and I prove by him that these active movements are not painful in the strict sense of the word. But they are laborious. The limb seems heavy and in order to move it the patient must make an effort which will have to be energetic at the start but which will become more and more easy as time goes on. It is precisely because this effort is necessary that the patient must be urged to do it without ceasing. Without this urging he will not make the effort which he regards as burdensome.

Real pain is rare, and when it occurs it is only transitory. It depends then either upon displacement of the fragments of the fractured bone or on the occurrence of intraarticular effusion. It happens indeed from time to time, during very active mobilization, that pain suddenly occurs together with functional impotence, and on examining the joint one will find effusion present. It will suffice to evacuate the fluid by puncture in order to have everything become normal again. There will also be real pain if the movements cause displacement of a large bony fragment, but in this case, as we shall see, the movements must be restricted. We shall see also that in purulent arthritis actual pain appears when the evacuation of the pus has not been complete and that in order to cause this pain to disappear it will suffice to effect complete emptying of the sac by more energetic movements and of greater extent. But except in the cases mentioned active movements are not really painful. The best way of assuring oneself of this is to observe the patient when he is not conscious of being under observation. We shall then see that the wounded man treated by active mobilization uses his limb in all sorts of ways not included in the method, which he certainly would not do if the movements were painful even in the slightest degree, for the man who suffers from movements of the limb instinctively keeps this limb quiet. Furthermore, the patient himself will often tell you that when painful sensations appear from time to time the best way of quieting them is to execute some active energetic movements. This is a fact which often causes astonishment to those unacquainted with the method, because we all know the extreme sensibility of joints treated by immobilization and we know incomplete immobilization will then excite lively pain. Joints treated by active mobilization have not this extreme sensibility and they do not shrink from movements. An extremely interesting phenomenon and one hitherto unrecognized is that sensibility of a joint which has been actively mobilized is absolutely different from that of an immobilized articulation. Immobilization increases the articular sensitivity, while active mobilization maintains it at a normal degree.

1. Immediate Active Mobilization in Non-infected Joint Lesions.—We are going to review now the different classes of non-infected joint lesions and we shall see in what way it is necessary to apply to each of them the principles we have described above.

A. *Joint Lesions without Involvement of the Bone.*—The most simple type of these lesions is furnished by traumatic hemarthrosis and hydrarthrosis. We have already spoken of these. In war surgery all the joint wounds should be treated in the same manner as long as they are aseptic, whatever may be the extent of the destruction of the soft parts. We find here simple perforations and large, uneven wounds opening into the joint, loss of substance of the skin, of the ligaments, or of the capsule, and, except in cases of simple perforation by a rifle or machine-gun bullet—in which case we may abstain from any interference—one must always excise widely along the wound, whatever may be its extent. That is the way we transform an infected wound into a surgical wound. When the wound is probably aseptic, that is to say, when the patient is received within twelve hours after the injury, we must close the articulation by suture, hermetically sealing it without drainage. That is the practice to which we all arrived at the front and the French surgeons did much to establish it. It gives infinitely better results than any other mode of treatment. It is indeed in joint wounds that primary suture finds its best application. But this suture must be complete at all costs and hermetically sealed. I follow this operation by immediate active mobilization or rather by immediate and complete restoration of function Thus in cases of the elbow joint active mobilization alone is to be considered, but when dealing with the knee we must add walking to articular mobilization just as we have seen in cases of simple hemarthrosis. The same method must be followed in cases of articular wounds with a projectile in the joint. Intraarticular projectiles should always be immediately removed, whatever their nature and size. We do a vertical arthrotomy, unilateral or bilateral, and remove the projectile, excising the wound of entrance, and then close it completely. One can always remove a projectile by a simple vertical arthrotomy, provided the incision is of sufficient length; it is never necessary to make a horseshoe or curved incision cutting the patellar tendon. This is not because this section prevents immediate active mobilization, but because it necessitates an extremely careful suture of the tendon and it is always better to avoid this. When the projectile occupies the posterior intercondylar space or the posterior aspect of the condyle it may be impossible to remove it through the lateral incision. In such a case, instead of making the horseshoe incision, I have added to the two lateral in-

cisions previously made a third one passing across the popliteal space behind and exposing perfectly the posterior aspect of the articulation. The dissection of the popliteal space is rather delicate, but if the incision is long enough one can easily avoid

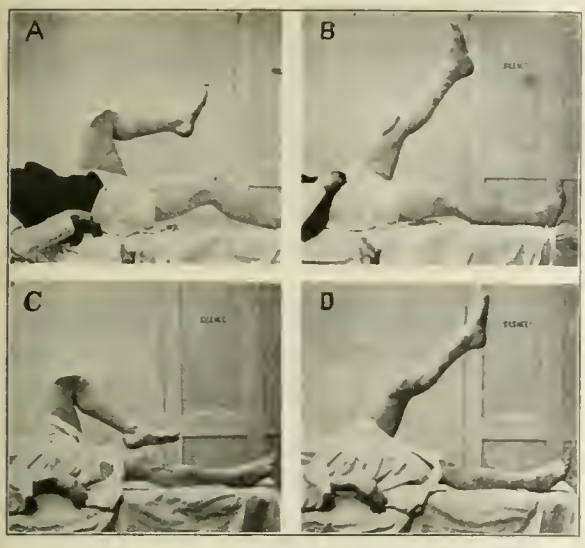

Fig. 1.—Maurice G. Wound of the left knee by a shell fragment passing behind the patella; projectile extracted and wound closed aseptically. A and B, flexion and extension one day after operation; C and D, flexion and extension after ten days.

the vessels and nerves, and after opening the synovial capsule the entire posterior aspect of the joint is exposed to view. This third vertical incision does not complicate the treatment by mobilization. I think this triple arthrotomy should be preferred to the horseshoe incision because it allows us to expose the joint cavity from behind just as well and even better, and because it has none of the disadvantages of a flap operation.

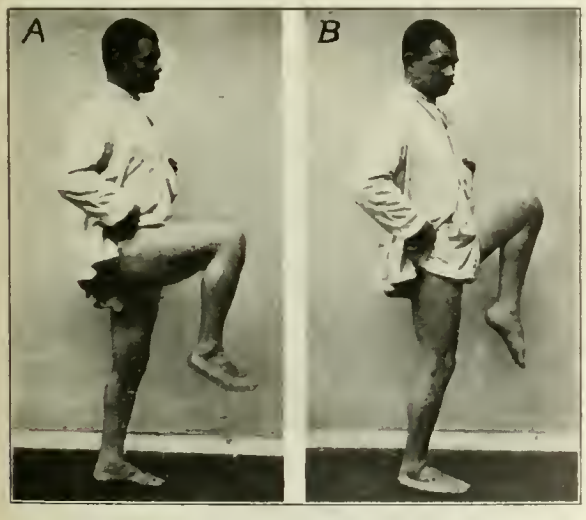

Fig. 2.—Same case as illustrated in Fig. 1. A, extension, the patient standing on the wounded leg; B, flexion, the patient standing on the sound leg; two months after operation.

After the removal of the intraarticular projectile the function of the joint should be immediately and perfectly restored just as it would be in case of lesion of the soft parts without enclosed projectiles. That is to say, the wounded man ought to begin to walk immediately in case of injury to the knee or begin immediately to make active movements when it is the elbow that is injured. These articular wounds with or without foreign bodies lend themselves perfectly to this mobilization and the results are just as good and just as rapid as in case of simple traumatic effusions. We obtain the restoration of function just as easily and the wound heals without complication. Thus wounds of this sort close in a few days, leaving behind them neither stiffness nor muscular atrophy. It is also true that the prognosis in lesions of this kind treated after my method is excellent.

There is one detail of the technique in arthrotomy for articular wounds which is important, and that is, we must suture the joint as far as possible in layers—synovia, capsule, and skin, in order to have a solid cicatrix which will not permit later a synovial hernia. It has happened to me to open the knee joint solely in order to get a better suture in this way. In case effusion occurs we must not stop the movements but evacuate the fluid and continue the mobilization. Of course it may happen that the joint becomes infected notwithstanding a careful and extensive excision of the wound. In war surgery one is never absolutely certain of having removed all the infected or contused tissue. The wounds of the popliteal space especially do not lend themselves readily to wide excision. If infection occurs we must reopen the wound or wounds and proceed as we shall describe below, but we must always bear in mind that when the surgical preparation of the wound is well made infection is rare. According to my statistics it is certainly not more frequent than when the articulation is immobilized after operation.

B. *Articular Wounds with Slight Osseous Lesions.*—In this category we find, first, simple perforations of the epiphysis, whether complete or incomplete, with retention of the projectile in the bone; secondly, erosion of the cartilage, detachment of chips from the surface of the bone, and more or less deep loss of substance, but limited in the surface extent. All these lesions have this in common, that they leave intact the greater part of the joint surface and that they are not accompanied by any line of fracture involving the epiphysis and delimiting a detached or detachable fragment. There is therefore no displacement, and the treatment is exactly the same as that of articular lesions without involvement of the bone, but completed by removal of the loosened or detached cartilaginous fragments, removal of bony splinters, extraction of the projectile and of the disorganized tissues due to it, the toilet of the osseous wound, and complete closure without drainage. Active, immediate mobilization must be at once instituted. In the case of the knee it will ordinarily at least be possible to have the wounded man begin to walk at once, unless the loss of substance involves some considerable extent of surface. A loss of substance of even considerable depth will be less disadvantageous than the detachment of a superficial chip of somewhat wide surface area. The most unfavorable condition for walking and also for final restoration of function is that resulting from an extensive loss of the cartilaginous covering, especially when two opposing surfaces are involved as, for example, the posterior surface of the patella and the anterior face of the condyles.

In such cases we have encountered considerable difficulty in the maintenance of mobilization, and an active collaboration of the patient alone makes it possible. These lesions are in this respect more serious than intraarticular fractures of greater

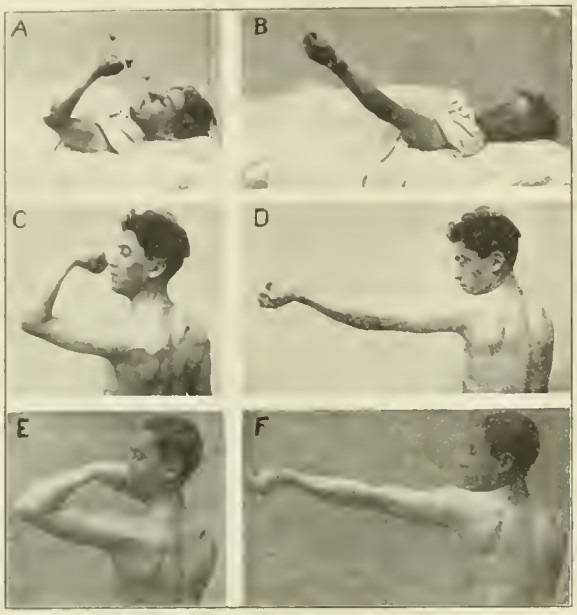

Fig. 3.—Georges de B. Penetrating wound of the left elbow by a large shell fragment lodged in the joint; no bone lesions; incision, extraction of the projectile, and closure of the wound; aseptic healing. The location of the projectile is shown in Fig. 4. A and B, flexion and extension on the day following the operation; C and D, flexion and extension after two weeks; E and F, flexion and extension at the end of one month.

gravity in which, however, the cartilaginous surfaces are less involved. We encounter sanguineous intraarticular effusions quite frequently in this class of lesions, due to the fact that the denuded surfaces are of considerable extent and continue to bleed for a while. It is important to puncture these hemarthroses immediately in order to prevent the blood from coagulating and the clots from attaching themselves to the roughened articular surface. Except when the involved surface of cartilage is extensive, active mobilization gives an infinitely more rapid cure than the classical treatment. The quality of the cure is also excellent. Articular movements are preserved intact and muscular atrophy, even if it is not entirely absent, is reduced to a minimum and does not interfere with function. It is in such lesions that immediate active mobilization excites the astonishment of the surgeon accustomed to immobilize all fractures. It also astonishes the patient who, like the surgeon, is imbued with the necessity of keeping a broken limb absolutely still.

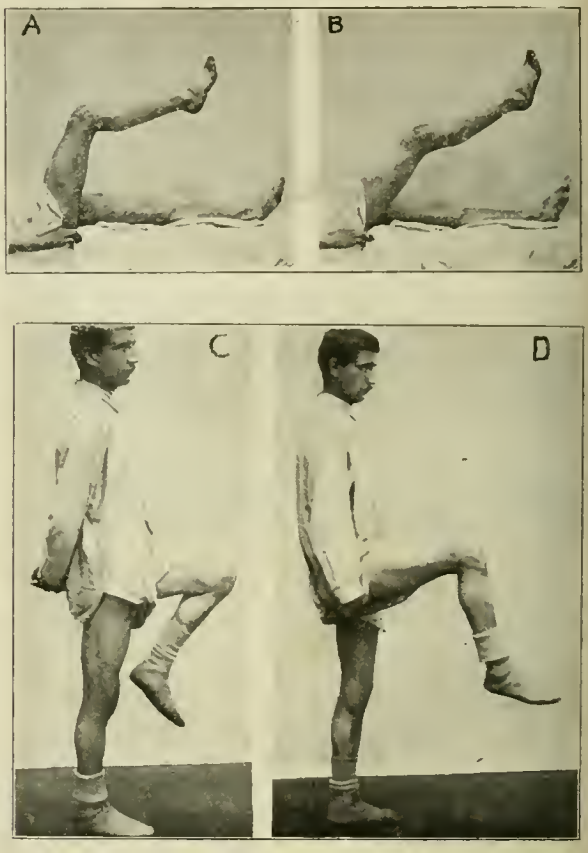

Fig. 5.—François H. Perforation of the right knee by a shell fragment with partial destruction of the patella; incision, esquillectomy, definite closure of the wound; aseptic healing, the patient beginning to walk after eight days. The injury to the patella is shown in the *X*-ray picture (Fig. 6). A and B, flexion and extension two weeks after the operation; C, extension after four weeks, the patient standing on the injured leg; D, flexion after four weeks.

Fig. 4.—*X*-ray picture showing the location of the projectile in the elbow of Georges de B. (Fig. 3)

Fig. 6.—*X*-ray picture of the knee of François H. (Fig. 5).

We must convince both of them immediately of the harmlessness of the method.

C. *Articular Wounds with Bony Lesions of Moderate Extent.*—By bony lesions of moderate extent I understand those that have caused detachment of a considerable part of the epiphysis or which will result in such detachment; such are the cases of transcondylar fracture. Even when the fragment is not entirely detached the joint line is interfered with and there is a lessened fixity of the epiphysis. The displacement would have the effect of modifying the form of the articular surface and so compromising its movements. Lesions of this class are therefore much more serious from the point of view of function than those of the first category. It is not that destruction of bone is necessarily more extensive; it is often less, but that which gives it the character of gravity is the danger of dislocation. It is this danger which calls for certain precautions to be taken in the treatment. This treatment calls for operative preparation of the joint just as in the case of the lesions described above, that is to say, excision of the contused soft parts, wide incision into the joint, careful toilet of the line of fracture, which one must separate somewhat in order to be able to remove by a small curette débris of all sorts which may adhere to the roughened surfaces, and finally a total suture, layer by layer, of the articulation.

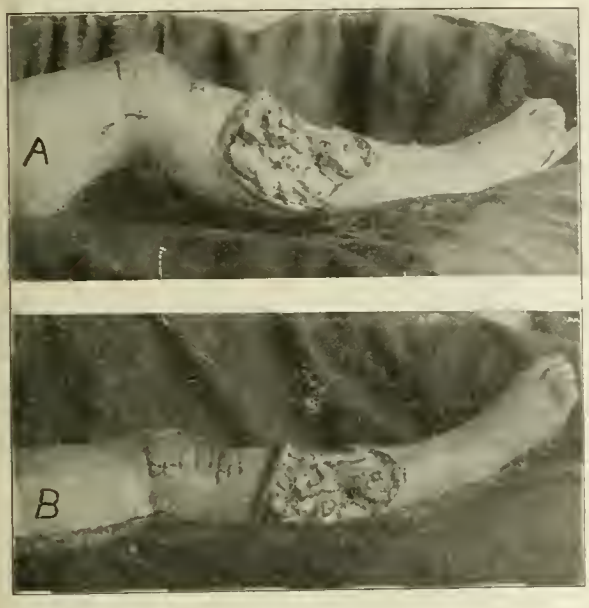

Fig. 7.—Jacques Van H. Multiple wounds of the right thigh and leg by grenade fragments; penetrating wound of the knee with fracture of the external condyle; comminuted fracture of the fibula; lesion of the sciatic nerve. (See Fig. 9.) Bilateral arthrotomy; total closure of the joint. Gaseous gangrene of the leg and phlegmon of the thigh, but between these two foci of infection the knee remained aseptic. A and B, flexion and extension two weeks after the injury.

Fig. 8.—Same case as shown in Fig. 7. A and B, flexion and extension two months after the operation; C and D, flexion and extension after five months.

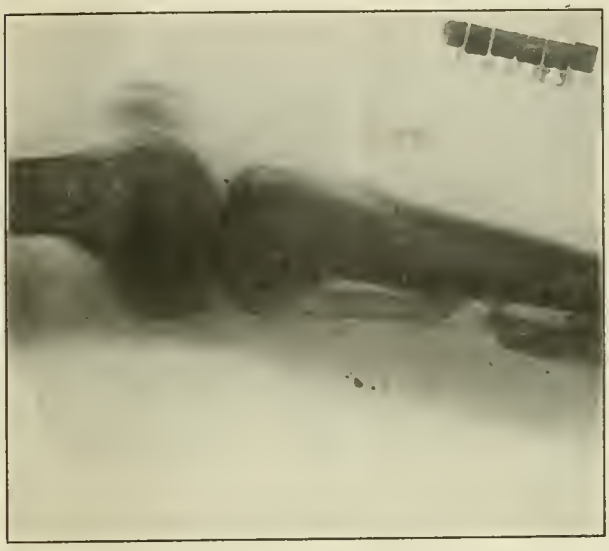

Fig. 9.—X-ray picture showing the joint injuries in the case of Jacques Van H. (Figs. 7 and 8).

If there are any foci of loss of tissue, they should be carefully cleansed as we have seen above, and if necessary we must practise esquillectomy. But I do not include in this group of moderate bone lesions those with a loss of substance of rather wide extent. I prefer to study these along with great bone injuries and to reserve the name of moderate bone lesions for those which simply modify the contour of the articular surfaces. After the operative preparation of these lesions, immediate active mobilization should be instituted, and it is no more difficult and no more painful here than in cases of joint lesions with injury to the bone which I have called slight. We can obtain the full extent of movement just as rapidly, and just as perfect results can be secured.

In cases of wounds of the upper extremity, especially of the elbow, there is no particular precaution to be taken and the limb can be immediately mobilized just as if we had to do with a slight bony lesion. The fracture heals within a short time and the function is perfectly preserved. An important point and one which is easy to verify by radiography

is that the line of fracture when the patient is making active movements does not become a point of departure of an interarticular exostosis as is too often the case in fractures of the elbow treated by immobilization. On the contrary the movements

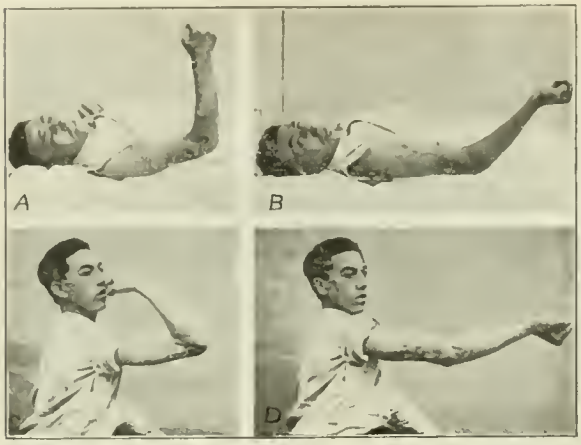

Fig. 10.—Georges Vander V. Extensive wound of the right elbow by a grenade fragment; two projectiles in the joint; almost complete destruction of the articular surface of the humerus. Foreign bodies extracted, esquillectomy, fixation of the external condyle to the shaft of the bone and to the internal condyle by means of a long screw (see Fig. 11). Wound completely closed; healing aseptic, though part of the cutaneous suture yielded as a result of too great tension; screw removed at the end of one month. A and B, flexion and extension after ten days; C and D, flexion and extension nine months after the operation.

direct the deposit of callus in an eccentric direction and drive it outside of the articulation. If occasionally some displacement of the fragment occurs it will never be toward the articulation but rather toward the shaft of the bone.

In case of the knee a certain amount of precaution is necessary and we must not permit immediate walking because of the danger of displacement. We must content ourselves first with mobilization

Fig. 11.—X-ray picture of elbow of Georges Vander V. (Fig. 10), showing the bone destruction and the fixation screw in position.

in bed; walking should be delayed until the time when the fracture is sufficiently solid to remove all fear of displacement of the fragment. The time required for this is about three weeks. After that time walking is permitted and the progress of the case is the same as in one with minor lesions. In all cases in which these rules have been strictly applied the patients have recovered with muscular integrity and without muscular atrophy.

D.—*Articular Wounds with Great Bone Destruction.*—In this group the anatomical lesions are extremely variable as regards form, localization, and extent, but as regards treatment we separate them into two groups, in one of which there is great loss of substance while in the other there is a comminuted fracture of the epiphysis. The lesion may involve one epiphysis or both.

1. *Great Loss of Substance of the Epiphyses.*—Here there is a loss of a considerable amount of one side of the epiphysis in such a way that there is no contact with the corresponding part of the other epiphysis—it is out perpendicular, as it were. The articular line at this place is interrupted by a considerable separation of the two bones. In the case of the elbow the function will not be greatly impeded since this articulation is not called upon to support great pressure. There will result simply a certain degree of curvature of the limb in the effort to approximate the two surfaces but the deformity will not appreciably affect the function. It is very different in the case of the knee where one has to fear that in bending toward the side where the loss of substance is great the articulation will lose the solidity necessary to bear the weight of the body and permit walking. This is one reason for the opinion held by many surgeons that since the result to be expected is bad we must not seek for a cure with preservation of mobility but rather resort to primary resection. This opinion does not seem to me defensible. I have resorted with success in these cases to conservatism with immediate active mobilization. I will not insist again upon the operative preparation of the joint and of the seat of fracture which ought to be done according to the usual way, and which will result here in the removal of a good part of the epiphysis. I will say, however, that I leave the bone cavities empty and do not attempt to fill them with any pastes. In the case of the elbow, the patient after operation can make movements of extension and flexion as [illegible]s if the lesions were slight, and the functional results will be excellent. At most there will be a slight lateral mobility but this will be reduced by use. In any case the result will be infinitely better than that following primary resection. Secondary resection will very rarely be called for if one has faithfully applied active mobilization.

The question is more complicated in the case of the knee. So long as the wounded man is in bed the procedure is exactly the same as in the case of less important lesions. Flexion and extension are equally well executed; but as soon as the patient rises and tries to walk the knee yields and the patient finds it impossible to bear his own weight upon it. This loss of power is, however, transitory and remediable. It is only necessary to get the patient some retentive apparatus such, for example, as a Thomas splint, articulated at the level of the knee, and then walking with flexion becomes possible again. Very often the apparatus can be removed after a few days and the wounded man will walk very well with a cane, and the lateral mobility which was present at first will be found

to diminish day by day until finally the patient will be able to discard even this support. In other cases the knee cannot be sufficiently fixed and the patient will need a leather articulated knee-cap to enable him to walk comfortably. It seems to me

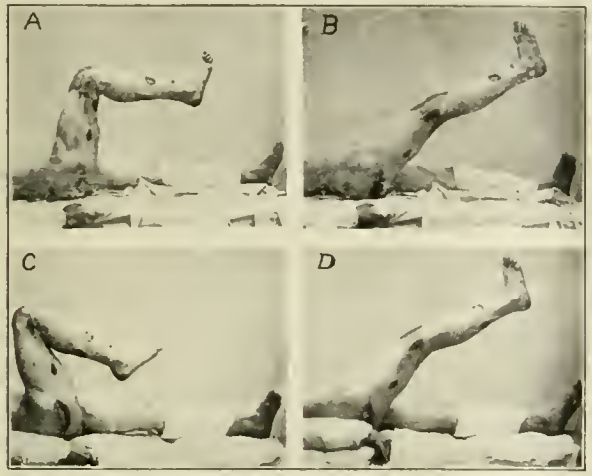

FIG. 12.—Georges S. Multiple wounds by bomb fragments. (1) Penetrating wound of the right hip with a long fragment impacted in the head of the femur and the border of the cotyloid cavity. The track of the missile was excised and the fragment extracted, the wound being left open. (2) Penetrating wound of the right knee. Excision of the wound surface followed by total closure of the wound. Immediate mobilization of the two joints was instituted despite the serious condition of shock. The wounds healed aseptically, the hip wound being completely healed after about one month. The patient was detained in bed for some time because of other wounds, especially of a fecal fistula opening beside the coccyx. A and B, flexion and extension two days after the operation; C and D, flexion and extension after five days. The final result is shown in Fig. 13.

therefore that primary resection is not indicated in the class of lesions which we are now considering.

It goes without saying that my method is not applicable when the bone destruction has passed beyond a certain point. We cannot absolutely fix the limits of this loss of substance, for one patient will get along quite comfortably with a knee which another one would be unable to use. There is, how-

FIG. 13.—Georges S. (Fig. 12); showing (A) flexion and (B) extension after five and a half months.

ever, a limit beyond which joint contact becomes manifestly insufficient, and in my experience this limit seems to be a loss of a little less than the lateral half of the epiphysis. In extreme cases such, for example, where the entire condyle or one-

half the head of the tibia has been lost, I advise trying conservatism and performing resection only secondarily when it is impossible to obtain sufficient joint stability. I advise the same in those cases of great loss of substance of both epiphyses

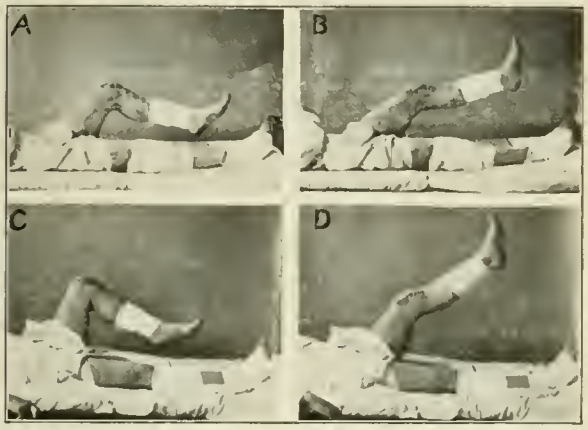

FIG. 14.—Emile C. Multiple wounds by bomb fragments; compound fracture of the left knee. Removal of the upper surface of the tibia, more than one-third of which was destroyed (see Fig. 17). Complete closure of the wound. At the end of one month the patient tried to walk, but the leg yielded laterally and he could not bear his weight on it; the application of a retentive apparatus (see Fig. 15) made walking possible. Later he was able to walk without this apparatus, and finally could dispense with the aid even of a cane. A and B, flexion and extension four hours after the operation; C and D, flexion and extension after five days.

where the anatomical conditions are even worse. It does not seem to me, however, in cases of this sort that it is the extent of loss of bone substance which is the principal factor to be considered; I think it is rather the condition of the crucial ligaments, and consequently the greater or lesser degree of union of the femur and tibia. When these ligaments are present I try to preserve the joint

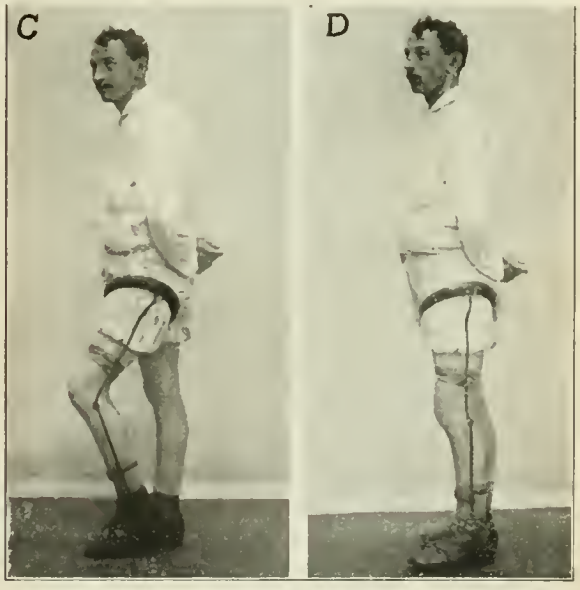

FIG. 15.—Emile C. (Figs. 14, 16, and 17); showing (C) flexion and (D) extension while walking with the aid of a light support, two and a half months after the operation.

by means of active mobilization. If this attempt fails there is always time to perform a secondary resection.

2. *Splintering of the Epiphyses.*—Comminuted fracture of the epiphyses constitutes a complex

lesion, yet may almost always be regarded as a T-fracture. There is a splintering of the condyles into multiple pieces, between which the upper fragment descends, with or without fracture of the patella; or longitudinal splitting of the tibial pla-

Fig. 16.—Emile C. (Figs. 14 and 15). A, extension; B, flexion possible several months after the injury.

teau with a pushing up of the shaft of the tibia; sometimes both lesions are present. These are, first of all, cases of fracture, and the articular lesion here occupies a secondary place. That is not to say, however, that active mobilization does not find its application here also. After incision into the joint, esquillectomy with removal of the detached splinters, and complete closure of the joint, we must

Fig. 17.—X-ray picture of the knee of Emile C. (Figs. 14, 15, and 16).

begin with the application of continuous extension. I employ for this a screw-extension apparatus which I devised during the war.

The extension brings into place the shaft of the bone and also restores to their proper position the adherent splinters. This reconstitutes the line of the articulation so far as the degree of bony destruction permits. From now on the wounded man, whose knee was absolutely powerless prior to the extension, can begin to make slight active movements. In order to render this possible the limb must rest simply on the hard surface of the bed and not be encased in a splint. The degree of mobility which can thus be obtained, and which will be preserved after consolidation of the fracture, will depend evidently upon the extent of the lesions and upon the measure of success attained in restoring the joint line by bringing together the dispersed fragments of bone. I may say, however, that mobilization gives excellent results, sometimes astonishingly so. I therefore do not advise resection in these grave cases, except as a secondary operation, after the attempt at conservation has failed either because of infection and resulting osteomyelitis, or because of secondary necrosis of a large number of the previously adherent splinters. One thing is certain, the surgeon who does not spare himself trouble—this treatment is long and fatiguing—will obtain astonishingly good functional results.

Much more even than in the case of the knee, comminuted fracture of the elbow should not, in my opinion, be treated by primary resection. Whatever the extent of the lesions, conservation with mobilization is always indicated. Undoubtedly we shall see cases of imperfect reduction of the fractures, of exuberant callus interfering with flexion, but one can always resort to a secondary operation of chiseling away a projecting fragment or an unduly large osteophyte. The functional result in such cases will always be infinitely superior to that obtained by primary resection. Indeed, I am convinced that primary resection should be absolutely banished from the treatment of comminuted fractures of the elbow.

My experience with osteosynthesis by means of transepiphyseal screws, or by plates in case of extensive destruction of the elbow joint, has not been very fortunate, although *a priori* such treatment ought to facilitate active mobilization by restoring at once the normal contour of the articular surfaces, and should insure a normal callus. After a first period, always short, in which the osseous fixation certainly facilitates the movements, I have generally seen the screws and the plates give rise to hyperostosis, and then the extent of possible motion is reduced, and I have had to remove the screws and plates. It is probable that this failure of a procedure which is *a priori* logical is due to the fact that in war surgery it is extremely difficult to render the seat of fracture immediately and perfectly aseptic.

The extremely conservative treatment which I advocate for extensive intraarticular fractures demands the expenditure of much time and great care. Consolidation is slow, and marked by numerous incidents, such as a constant struggle against infection of the wound, necrosis necessitating repeated sequestrotomies, difficulties in technique for obtaining active mobilization, etc. But one who will not let himself be discouraged by these difficulties, and who will devote to it the necessary patience, will obtain unhoped-for results.

(*To be concluded.*)

MEDICAL RECORD.

PROPHYLACTIC VACCINATION AGAINST PNEUMONIA.

THE specific treatment of pneumonia is at present limited to the serum treatment of Type I infections, and while efficacious to a certain extent fails in a goodly number of cases, either because they come under observation too late to benefit by the treatment or because the toxemia is too virulent to be overcome by the means at our command. This infection is peculiar among the infectious diseases in that one attack does not seem to leave behind it any immunity to succeeding attacks and for that reason it has seemed unreasonable to expect good results from attempts to make use of prophylactic treatment. Nevertheless the attempt has been made and the published results of Cecil and Austin (*Jour. Exp. Med.*, 1918, xxviii, 19) show a distinct diminution of incidence of pneumonia due to Types I, II, and III during a period of ten weeks following the vaccination of 12,519 men at Camp Upton with a vaccine composed of these three types of pneumococcus. There was also a lowering of the incidence of pneumonia due to Type IV pneumococcus and to the streptococcus. These results were so encouraging that when the disease became prevalent in the Army Camps during this past winter, a more extensive trial of this procedure was made.

The report of the results obtained at Camp Wheeler is made in a paper by Cecil and Vaughan (*Jour. Exp. Med.*, 1919, xxix, 457) and certainly seems to justify great expectations from this method of protection, especially where large bodies of men are assembled together, where the opportunities for the spread of the disease are most favorable. There had been some trouble experienced with the use of a saline vaccine, in that three doses were considered necessary and that small sterile infiltrations occasionally followed its administration. It was found that a pneumococcus lipovaccine produced good immune reactions so this was adopted for use at Camp Wheeler. The preparation contained pneumococci each of Types I, II, and III, and was made up in cottonseed oil containing 2 per cent. of lanolin, a mixture found not to be irritating to the subcutaneous tissues. The population of the camp was vaccinated as soon as possible, and after that was accomplished most of the new recruits were vaccinated within 24 hours after their arrival in camp. All those who objected to taking the vaccine were passed by. In all 13,460 men received the vaccine, a number constituting eighty per cent. of the camp strength. The reactions were less marked than those produced by the triple typhoid lipovaccine. There were only five severe local reactions and only 0.7 per cent. were ill enough to be admitted to the Base Hospital. The symptoms complained of were chiefly headache, general aching pains, chill, and sore throat. The vaccinations were begun on September 21 and the observations were concluded on December 20. The period of observation lasted, therefore, from two to three months, for the new draft was completed by November 2. The total results without correction or classification are impressive. Among 13,343 vaccinated the incidence of pneumonia was 26.1 per 1000 and among 3,378 unvaccinated was 68.3 per 1000, 2.6 times as large. Certain groupings of these men show the results to be even more favorable than the total figures indicate. For instance, among seasoned men the rate was for vaccinated 7.2 and for unvaccinated 46.4 per 1000. It was shown that immunity against the pneumococcus does not begin to develop until the eighth day after the injection of the lipovaccine and if the above figures are corrected by deducting all those cases which developed during the first week after inoculation, the difference between the vaccinated and unvaccinated is most striking. It must be admitted that the figures presented in these two reports are most convincing as to the value of this procedure and the evidence seems to indicate that the immunity produced will last for at least two months. The figures are not, however, classified so as to show variations during successive periods following the inoculation.

In this connection it is interesting to recall the facts of the first extensive study of the results of the preventive inoculation for pneumonia published by Wright ("Preventive Inoculation Applied to Pneumonia in the African Native." New York, 1915). He obtained a reduction of about fifty per cent. in the incidence of the disease in very large numbers of natives employed in the mines. His was a saline vaccine, given in two doses of 1000 millions each. Its composition in respect to the types of pneumococcus now recognized, is of course unknown. One important observation of Wright's was that after two months had elapsed following inoculation, the incidence among the vaccinated and the unvaccinated was practically the same. The death rate was favorably affected over a much longer period. It will be seen that the results of this later work show a considerable advance during the intervening time. The classification of pneumococci into types has in itself assured more generally efficacious results and there is no reason to believe that in the future some of the strains now grouped in Type IV may not be separated out into independent types. Means for the detection of anti-

bodies in the blood of inoculated individuals have been refined and there is some reason to believe that the use of an oily base for the bacterial suspension leads to the development of a higher degree of protection. Surely there is much justification for the conclusions of Cecil and Vaughan that, "If methods can be devised for still further reducing the toxicity of the pneumococcus vaccine, and if active educational propaganda is instituted in its behalf, there is no reason why vaccination against pneumonia should not find a large field of usefulness in civilian as well as in Army life."

THE DIAGNOSIS OF THE SYPHILITIC CHANCRE.

SPEAKING in a general way, the diagnosis of syphilitic chancre is easy, yet in practice much difficulty may arise. No faith must be placed in the dogma that the hard sore is always single, because in a certain number of cases there are several. In these circumstances it is probable that autoinoculation is the cause, immunity not being complete until the lapse of about ten days, according to Queyrat. Next comes the question of size, which has been generally stated to be about fifteen millimeters in diameter, but in practice it is not uncommon to meet with the so-called giant chancre. Induration is always present, but the physician must know how to look for it. If large chancres are seized in their largest diameter, it may escape detection, so the sore should be palpated in its lesser diameter or at its edges. On the other hand, pigmy chancres are so indistinct and their symptomatology so very limited, that their diagnosis may not be made unless an ultramicroscopic examination of the secretion is made.

The satellite adenopathy is of great diagnostic value, but it bears no relationship to the development of the initial lesion. Polyglandular, indolent, and aphlegmasic, it represents, with the duration of the period of incubation, one of our best diagnostic elements, but if, as occasionally happens, these lymph-nodes suppurate, there is considerable risk of an error in the diagnosis. It must also be recalled that chancres of the meatus have, on account of careless examination, been diagnosticated as gonorrhea.

Among the complications which make the diagnosis difficult should be mentioned phimosis, in which case the prepuce is in a state of high-grade edema making palpation of the underlying sore a matter of great difficulty, and its induration practically impossible to detect. In phimosis cases there is not uncommonly a mixed infection with ulcus molle causing the clinical aspect of the case to become an intricate problem from the viewpoint of diagnosis. An ordinary herpes when treated with antiseptic lotions may frequently become indurated, a fact never to be forgotten.

Therefore, in all doubtful cases laboratory methods must be employed, be it the direct search for the treponema in the secretion of the sore or the specific reactions obtained from the patient's blood serum. In order to discover the presence of the *Spirocheta pallida* it must be rememberd that this organism is always deeply seated in the histological structures of the chancre and not on the surface of the lesion, and that the ultramicroscope must be used or the method of scraping the lesion be employed, the products being examined by the india ink technique. As to Wassermann's reaction, it is frequently difficult of interpretation, as is well known. The reaction will not be positive until the lapse of from fifteen to eighteen days and is more than likely to be very weak during the first phase of syphilitic infection. If at the end of this time it is found to be negative this fact does not in itself absolutely eliminate the diagnosis of lues. However, when it is positive, it is an absolute confirmation of the diagnosis of syphilis, at least in most instances.

These remarks are unquestionably commonplace, but nevertheless are practical and they would not be called for were it not for the fact that the medical profession at large often falls down most unpardonably in the diagnosis of the initial lesion of a disease which, in the twentieth century, should be thoroughly cognizable to all.

THE PHYSIOLOGICAL WEIGHT.

WORRY over underweight is common, but if the subject is healthy and efficient and receives his due share of nourishment, there seems no sound cause for worry when the problem concerns the individual. Such a one may be technically uninsurable, but this does not connote a bad prognosis for life. As a result of a special study, Leven, in the *Gazette des hôpitaux* for April 17, reaches the conclusion that any weight is physiological provided the subject is healthy as shown by thorough examination. In many cases of emaciation, in which latent cancer is suspected, treatment of indigestion, plus nourishing regimen will restore the weight of the subject. Excess avoirdupois does not represent physiological weight, if due to superalimentation, and many of this class are also technically dyspeptic, having many symptoms of that condition—some of course due to inability to digest the food excess. Dyspepsia then has no inevitable relationship to weight, and we simply have fat and thin dyspeptics along with those of average weight. The author does not refer to the remarkable fluctuations in weight seen especially in women, which seem conditioned chiefly by change in the ability of the tissues to retain water. He rightly eliminates the question of normal weight in subjects under 25, and it is during this period that paradoxical fluctuations are often seen. He cites the fact that mere over-eating does not fatten a man predestined to be thin, or, in other words, does not necessarily increase the phsiological weight. A man can overeat himself into dyspepsia and in time the latter may result in a loss of weight. Again underfeeding does not bring a man below his physiological weight

until a considerable interval has elapsed. Overwork does not necessarily cause lowering of the normal weight.

The subject is of interest because every man may be said to have a normal weight, although this may be and doubtless is ignored under ordinary conditions. Let the subject change his environment and occupation and diet and paradoxical results may be in order which are rationalized by the conception of an inherent physiological weight. One subject does not reduce under a more active life or underfeeding while another fails to gain under fattening regimen and sedentary existence. It might profit the average man to feel out his probable inherent weight, for this factor would possess considerable value in a diagnosis of suspected disease.

CHRONIC ALCOHOLISM IN SWITZERLAND.

SWITZERLAND has been described as a country without a drink problem, although private stills are in common use and certain city bars subsist entirely on the "early morning" trade. Now and then a local practitioner intimates that the damage traceable indirectly to drink is not inconsiderable, although he does not enter into particulars. In the *Correspondenz-Blatt für Schweizer Aerzte* for March 1, Koecklin states that the Swiss practitioner as a rule does not treat chronic alcoholism although he is very familiar with its phenomena. There must be reasons for this aloofness, and one is the disposition to ignore conditions brought on oneself. But there is contributory neglect in many other affections, so that this pose cannot be upheld consistently. A man ill from drink cannot draw sick benefits and cannot be regarded as other than a victim of viciousness rather than of illness in the ordinary sense. He is therefore left to the philanthrophy of uplift societies composed of laymen. The busy practitioner engaged in treating genuine illness should not be asked to cater to him. Again when he reaches a certain degree of alcoholism the institution claims him and the practitioner associates the alcoholic with institutional treatment. He is of course ranked in this and other respects with drug addicts.

But certain drink cures have taught that the alcoholic is amenable to ambulant treatment and need not be interned and isolated from his normal activities, and the practitioner must take account of this possibility in his daily routine. The treatment is very largely psychic although drugs are quite capable of an occasional cure. The author in this connection, with especial regard to prevention of periodical sprees, places his patients on a bromide cure. The daily dose must be small and the material selected with care. The patient must have full insight into his condition. Several cases cited by the author reveal severe endogenous neuropathy amounting practically to periodical dipsomania. Bromine was begun when the first depressive sensations were noted and served to abort the drink crises. In some of the cases epilepsy and circular insanity were at the bottom of these crises. Heroinism and morphinism showed a similar response to bromine. The author prefers the newer organic bromides to the alkaline salts. His ideas and practice are of course old with us, but his dependence on mere bromides to the disregard of powerful alkaloids is worthy of attention.

SACCHAROSE IN CONSUMPTION.

THE accounts hitherto published on this subject have either been tinged with undue optimism by the discoverer, Lo Monaco, and his pupils, or dismissed with finality by some of those who have tested the remedy for themselves. One author alone, Mestre, formerly of the Pasteur Institute of Paris, seems to share the enthusiasm of the discoverer and upon his recommendation to test the subject Dr. von Schulthess-Rechberg, a Swiss practitioner, has pursued an independent research, his finds being published in the *Correspondenz-Blatt für Schweizer Aerzte* for April 12. He was not the first Swiss to test the treatment, for Bodmer after a trial warned against too much optimism. The author treated 9 patients, all in the third stage; so that any possibility of cure was remote. The one thing which the treatment can be trusted to secure is a diminution in the daily amount of sputum. In the usual case this suppression varied greatly—from 20 to 88 per cent. This result would seem to justify further research along the lines thus far developed. The author was unaware when he composed his paper that saccharose has a powerful action in diminishing excessive secretions of all kinds, but later secured through Bodmer the literature of this extension of the subject. Saccharose is even under trial for gonorrhea.

CONTAGIOUSNESS OF A HEALED CHANCRE.

THAT a clinically healed primary lesion may be contagious is not impossible in theory for a few virulent spirochetes might persist in the fresh scar and be loosened by the friction of coitus. But actual cases of such transmission are not common in literature, so that an observation by Narbel in the *Correspondenz-Blatt für Schweizer Aerzte* for April is worthy of reproduction. On January 21 of the present year a man presented himself with a chancre in the balanopreputial fold, a hard chancre, which to the microscope presented many spirochetes. The Wassermann was then negative. The patient was at once placed on a series of injections of novarsenobenzol, and between January 22 and March 1 received 7 intravenous injections of the drug comprising in all 4.65 gm. The ulcer had completely healed by February 1. On February 16, while still under treatment, the patient had intercourse with his mistress. He believed himself well and flatly disobeyed his orders. On March 17, or more than a month later, the woman appeared with chancre of the vagina near the ostium and enlarged inguinal glands. Her lesions contained numerous spirochetes. The mechanism has already been suggested. During the healing process certain spirochetes become enclosed in the neoplastic cells of the healing chancre and are liberated during the act of copulation.

News of the Week.

Opposition to Compulsory Health Insurance.—The Medical Society of the County of New York, at its stated meeting on May 26, passed resolutions approving of the instructions against compulsory health insurance given by the House of Delegates of the Medical Society of the State of New York to its delegates to the House of Delegates of the American Medical Association, and confirming these instructions to such members of the House of Delegates of the American Medical Association as are members of the Medical Society of the County of New York. Vigorous objections to compulsory health insurance were voiced by most of the speakers at a meeting of the social insurance department of the National Civic Federation on May 24, where it was pointed out that compulsory health insurance had proved a falure in England and Germany, had enormously increased malingering, and had effected no decrease in the death rate.

A Proposed Discussion of Narcotic Drug Addiction.—A petition signed by fifty members has been presented to the president of the Medical Society of the County of New York calling for a special meeting of the society for the purpose of discussing the narcotic drug situation and especially the amendment to the sanitary code of New York City, which has been prepared by the health commissioner. The petition recites that, "although the text of this proposed amendment has never been submitted to the medical profession either by the commissioner of health or by the public health committee of the County Society, its reported provisions, as gathered from the newspapers and from public utterances of the commissioner of health, constitute a radical and serious extension of the executive and administrative powers of the Department of Health over the treatment of private patients by the practitioners of this city, and over the hitherto legally protected confidential relations between them and their patients."

Nurses as Anesthetists.—Mr. James Taylor Lewis, counsel for the Medical Society of the State of New York, urges the restriction of the administration of anesthetics to licensed physicians and the exclusion of nurses from doing such work during surgical operations. He points out that as the law now stands it prohibits any one without a doctor's license from giving ether or chloroform or other poisonous gas to a patient except when directly and continuously supervised by a physician. Mr. Lewis contends that criminal action should be brought to prevent the continuation of this practice in certain hospitals, not only because the law is being violated but because human lives are being endangered. He states that the nurse who gives an anesthetic, must keep the tongue up, must watch the pulse, must pass upon the strength of the pulse, the color of the lips, the color of the skin, the condition of the skin, and other symptoms, and that all this is diagnosing the physical condition, and even diagnosing the presence or absence of disease, according to the definition of diagnosis on our statute books. He says further, "The operating surgeon can give no attention to the effects of the anesthetic, and if the nurse notices symptoms that indicate that the patient is 'going bad' the responsibility of taking action is hers and she must prescribe." He states also that in a suit growing out of the death of a patient where the surgeon had voluntarily employed an anesthetist who was not licensed, he would in the event of his brother physicians testifying in this case certainly be held responsible. A hospital would also in turn be held responsible if it permitted unsupervised and inexperienced women to give anesthetics, whether they were graduate or pupil nurses, because the employment of such inexperienced persons cannot be pleaded by them as a bar to an action against such institution where damage or death ensues.

New York City's Health Record for 1918.—The annual report of vital statistics, made public by Dr. W. H. Guilfoy on May 21, shows that the death rate for the year was 17.30, an increase of nearly three points over that of the preceding year. This increase was entirely due to the influenza epidemic. There were only 196 deaths from typhoid fever, as against 229 during 1917, and there were no deaths from typhus fever. There was an increase of 230 deaths from measles over the preceding year, while the number of deaths from diphtheria decreased by 158. There were 665 deaths from whooping cough, as against 489 in 1917. There were 8,779 deaths from tuberculosis in 1918, as against 8,825 in 1917. The report states that 4,139 persons died from cancer, with a rate of 84 per 100,000 of the population as against 4,867 and a rate of 85 during 1917. The statistics show that influenza had no effect on organic, heart and kidney diseases. From these causes 17,374 died in 1918, as against 17,829 in 1917. The general infant mortality rate was 92 per 1,000 births, as against 89 per 1,000 in 1917. From September 14, 1918, to March 10, 1918, there were 15,000 deaths reported from influenza, 6,600 from broncho-pneumonia, and 10,775 from lobar pneumonia, 32,785 deaths all told from these causes. The annual death rates from these causes for the quinquenium 1913 to 1918 averaged 10,996. The number of births reported was 138,046, as compared with 141,564 in 1917, and 137,644 in 1916. The birth rate was 23.51 per 1,000 of population which is the lowest probably in the history of the city, the number of marriages was 56,733 with a rate of 9.66 per 100,000 of the population as against 59,212 during 1917. The lowered marriage and birth rates are attributed to the various influences exerted by the war.

Fordham Medical School Closes.—Due to lack of funds to maintain in operation a first class medical school, the trustees of Fordham University announce that the Medical School of that institution will not resume its classes next September. An effort will be made to secure an endowment fund and if this is successful the Medical School will be reopened. The institution since its organization has conferred the degree of Doctor of Medicine on 377 students. There are at present 297 students 68 of whom are in the graduating class and will receive their degree this month.

The Norwegian Hospital of Brooklyn, which was turned back to the hospital authorities by the

War Department on December 1, 1918, and later taken over by the Treasury Department for war risk insurance cases, is to be returned to the hospital authorities not later than July 1. This step has been taken because of the protests against the latest transfer of the residents of that locality because of lack of hospital facilities in that district.

Antituberculosis Campaign Launched.—The New York State Department of Health and the Tuberculosis Committee of the State Charities Aid Association has initiated a state-wide campaign against tuberculosis by instituting a series of clinics to deal with the examination of those who have recently become affected with or exposed to tuberculosis. Thirty-four counties will have these clinics at their disposal, the number in each county to be determined by the number of existing cases. The reason given for the vigor with which the campaign is to be prosecuted is that there has been an increase in the number of cases of tuberculosis since the influenza epidemic. In order that a sufficient number of medical experts may be on hand in any of the districts, the superintendents and other members of the medical staffs of tuberculous sanatoria will participate in the work.

County Laboratory at Auburn.—The Cayuga County (New York) Board of Supervisors have appropriated the sum of $5,000 for the establishment of a county laboratory at Auburn.

Fee for Reporting Communicable Diseases.—Reporting communicable diseases in the township of Islip, L. I., has been stimulated and made more efficient by observing the law authorizing the payment of twenty-five cents to physicians for each case reported. Islip has a population of 20,000 and the amount paid to twelve physicians for the year 1918 was $640, or an average of $53 to each physician.

Another County Tuberculosis Hospital.—Herkimer County, N. Y., has sold $150,000 worth of bonds for the building of the County Tuberculosis Hospital in the town of Salisbury. Bids for the construction of the hsopital will soon be asked for.

Employment Bureau for Nurses.—The Atlantic Division of the American Red Cross announces from its headquarters at 44 East Twenty-third Street, that it is endeavoring to find suitable employment for the thousands of nurses who are being returned from service in Europe. The division has created an employment bureau of national scope for this purpose, and all returning nurses are asked to register with the bureau as they pass through New York.

Physician Builds Hospital Without Aid.—Dr. Gedney Jenks of Hastings-on-the-Hudson has just completed a two-story hospital building which he began in 1916 and has constructed with his own hands. He first undertook to raise funds for a hospital by subscription, but as he did not meet with a hearty response, he decided to erect the hospital himself. The hospital contains wards and operating room complete in every essential. Dr. Jenks, when the war began, enlisted for overseas service. The people of Hastings being thus left without a doctor asked that he be returned. He was sent back and resumed work on his hospital.

Lieutenant-Commander Joel T. Boone of the Navy Medical Corps has been decorated with the Croix de Guerre by the French Government for bravery at Vierzy, Belleau Wood, Soissons, and other engagements. He has also received the Distinguished Service Cross.

Major General William C. Gorgas, head of the American Yellow Fever Commission to Ecuador, arrived in Panama with his party on May 31 en route for the United States.

Professor Pedro Chutro of Buenos Ayres, who during the war was at Buffon Hospital, Paris, where he gave his attention largely to plastic bone surgery, has been demonstrating his methods at the Polyclinic Hospital, New York. He came to this country for this purpose on the invitation of the United States Government.

Dr. Mary M. Crawford of New York is to head the second relief unit to Serbia which is being sent under the auspices of the American Women's Hospitals. The unit expects to sail before July 1.

Charitable Bequests.—Among the bequests made by the will of William A. Slater is a legacy of $100,000 to the William W. Backus Hospital at Norwich, Conn.

New York Entertains Foreign Guests to Meeting of American Medical Association.—The New York City Committee on Reception and Entertainment of Delegates to the American Medical Association formally received the foreign delegates on June 2 at the Hotel Waldorf Astoria. They were received by the Mayor of New York City, the Commissioner of Health, the Commissioner of Charities, the President of the Board of Aldermen, the borough presidents, and the deans of the New York medical schools. The program for the week included tours of inspection of the public buildings and hospitals of the city, and the institutions conducted by the Department of Health and the Department of Charities. Special clinics were arranged by the various hospitals for Wednesday, and many social entertainments were interspersed in the program.

Obituary.

JAMES EWING MEARS, M.D.

PHILADELPHIA, PA.

Dr. J. Ewing Mears died at the Presbyterian Hospital, Philadelphia, on Wednesday of last week, after a long illness. He was born in Indianapolis, on October 17, 1838, and was educated at Trinity College, Hartford, and the Jefferson Medical College, Philadelphia, receiving his degree in medicine from the latter in 1865. During the Civil War he served as captain and quartermaster of the Indiana Volunteers, and later as medical cadet and acting executive officer of military hospitals. He was lecturer on practical surgery, and later clinical lecturer on gynecology, at the Jefferson Medical College, and professor of anatomy and surgery at the Pennsylvania College of Dental Surgery from 1870-1898. He was a fellow, one time president, and for ten years editor of the Transactions of the American Surgical Association; a member, one time

president, and for fifteen years editor of the Transactions of the Philadelphia Academy of Surgery of the College of Physicians of Philadelphia; honorary member of the Lehigh County (Pa.) Medical Society and of the Medical Association of Georgia. He was for several years surgeon in chief of the Pennsylvania National Guard. Dr. Mears was the author of a work on "Practical Surgery," and was a frequent contributor of surgical and other articles to the medical press.

FREDERICK PORTEOUS HENRY, M.D.

PHILADELPHIA, PA.

Dr. Frederick P. Henry died at Philadelphia, on May 24, at the age of 75 years. He was born in Middlesex County, N. J., July 21, 1844, and was graduated from Columbia University, College of Physicians and Surgeons of New York, in the class of 1868. He was at various times professor of medicine in the Woman's Medical College of Pennsylvania, physician to the Philadelphia General Hospital, lecturer on medicine in Jefferson Medical College and physician to Jefferson Hospital, and professor of medicine in the Philadelphia Polyclinic. He was a member and one time president of the Pathological Society of Philadelphia; a Fellow and honorary librarian of the College of Physicians of Philadelphia; a member of the Association of American Physicians, of the Philadelphia County Medical Society, of the Society of the State of Pennsylvania, and of the American Medical Association. He was author of a work on "Anemia," edited one of the editions of "Flint's Practice of Medicine," and was a frequent contributor to medical periodical literature.

Correspondence.

THE NARCOTIC DRUG QUESTION.

To the Editor of the Medical Record:

Sir:—Two events of great importance to medical men during the last week in May were the meetings in this city devoted to the consideration of the Narcotic Drug Situation. The first of these was the stated meeting on May 26 of the Medical Society of the County of New York, at which meeting the entire scientific session was devoted to this question. From the program as here given it will be seen that this presentation was entirely devoted to the legal, judicial, and administrative aspects of the situation.

1. Digest of the Federal and the State Narcotic Drug Laws, by George W. Whiteside, Esq., Counsel of the Medical Society of the County of New York.

2. U. S. Court Decision on the Narcotic Drug Law, by Benjamin A. Matthews, Esq., Assistant to the United States District Attorney.

3. Rules and Regulations of the New York Department of Narcotic Control, by Walter A. Herrick, Esq., State Commissioner.

4. The Narcotic Addict in Relation to the Health Department, by Royal S. Copeland, M.D., Health Commissioner.

5. The Law and the Narcotic Addict, by Cornelius Collins, Esq., Justice Court of Special Sessions.

6. The Narcotic Addict in Relation to the Department of Corrections, by James A. Hamilton, Commissioner of Corrections.

No speakers were scheduled to discuss these papers. It was generally understood at this meeting that the health commissioner was contemplating certain amendments to the sanitary code relating to the control, identification, and classification of drug addicts. On this account the chairman of the public health committee of the society was asked from the floor for a report on this matter, to which he replied that he had none to make.

In the informal discussion that followed it was stated that the members of the society who had given time, labor, and thought to the narcotic problem were under obligations which they duly acknowledged to the purveyors of this program for bringing together an array of their legal coadjutors on this question hitherto unequaled in number and distinction. This situation was likened to one in this city some time ago, where an assistant district attorney was deputized by the Mayor to welcome a convention of merchant tailors, then meeting here for the first time. This he did on behalf of his superior, and then on his own behalf for giving him an opportunity to welcome under one roof the greatest collection of his creditors that he had ever had the pleasure of seeing assembled together at one time.

The other meeting was the much heralded one of the organization to be known as "The Mayor's Committee on Public Welfare," which was the outcome of a conference at City Hall to discuss ways and means of controlling or suppressing the sale of habit-forming drugs and the regulation and distribution of chemicals of a high explosive nature. The full account of this meeting published in the daily papers makes it unnecessary to give any of its proceedings in detail. A noticeable omission was the failure to connect the subject of drug addiction with that of high explosives. Drug addiction, it is true, has been associated heretofore with all forms of crime and depravity by the legal and police departments, but its connection with TNT and similar agents of destruction had never before even been hinted at. In all public movements at this time an "angel" is an absolute necessity. One was not lacking at this meeting, who promptly responded when his name was suggested as chairman of the finance committee.

Among the measures proposed at the Mayor's meeting was a revision of the sanitary code compelling the registration of all those considered as drug addicts by the health authorities before they could be treated by a physician. According to the corporation counsel, this amendment will not involve the violation of the privilege of professional secrecy contemplated by the health commissioner. It is this innovation that has compelled the call just issued for a special meeting of the Medical Society of the County of New York to give voice and a hearing to the medical side of this question, which has been completely ignored by the municipal and health authorities to the detriment of the public, of the practicing physician, and of the profession of medicine.

John P. Davin, M.D.

117 West Seventy-sixth Street.

THE HEALTH COMMISSIONER AND THE NARCOTIC DRUG SITUATION.

To the Editor of the Medical Record:

Sir:—At the hearings before the Whitney joint legislative committee the bulk of experienced and official testimony was strongly toward urging honest, reputable practitioners of medicine to try to the best of their ability to treat and care for narcotic drug addicts in their medical practices. The reasons given for this were that the practitioner of medicine was the most logical and natural one to care for a sick person, and that, especially from the standpoint of the United States Internal Revenue officers and others, illicit traffic in the drug by the underworld would be materially reduced if the average medical practitioner would take care of as many addicts as he honestly and legitimately could.

The report of the Whitney committee stated that "any physician who refuses to prescribe for an honest addicted sick person is not living up to the high standards of his profession." Judge Collins has joined in the appeal for honest, reputable doctors to undertake the treatment and care of addicts. A good many honest, reputable physicians have answered the appeal and are doing the best they know and can to help the addicted sick. They have done so because it has been asked of them, because it is their professional duty and obligation to attend to the needs of the sick, and because it has offered and presented a new and interesting disease study; and the United States Internal Revenue officials in charge in the city of New York have been very wise and conservative, and have encouraged the honest, reputable physician to do the best he knew how.

The result has justified the appeal. According to the reports of Judge Collins, the illicit traffic and peddling in the drug has been almost entirely eliminated. While a certain amount of abuse in the prescribing and dispensing of narcotic drugs on the part of some physicians to addicts has arisen, yet according to the statement of Judge Collins it cannot be compared in the seriousness of its menace and danger to the community with the evils of illicit traffic and peddling by the underworld. But this result and this encouragement of doctors to undertake this work promise to be negatived by the unfortunate and misleading publicity fostered by the attitude and statements of the health commissioner of the city of New York. The trouble is that not enough honest, reputable doctors have entered upon this work of caring for the addicts; and the preaching of the thunders and the terrors of the law and the ordinances by the commissioner does not conduce, to say the least, to encourage members of the medical profession to give that cooperation so much desired by the more experienced authorities, and to care for the drug addict.

Not that the members of the medical profession want to evade laws or ordinances intentionally or to be above them. Treatment and care of narcotic drug addicts as diseased persons constitute a new line of medical thought, a new line of medical endeavor for the great generality of the profession. Neither the principles underlying the nature of the condition nor the methods of treatment or lines of handling have been worked out in a form of general acceptance. Honest mistakes, based upon honest errors of judgment, in honest study and application to the problems involved, may unintentionally lead to a transgression of the line laid down by administrative officials who have no conception of or sympathy with medical thought and practice; and owing to the uncertainties of the interpretation and application of the laws and ordinances by various officials it is not a pleasing or encouraging prospect to be compelled to defend one's doings in this honest endeavor, in highly expensive litigation, with honor, prestige, fortune, and everything else one holds dear in this world at stake.

What is necessary, however, to gain—and which surely will gain—the cooperation of the medical profession, is a clear exposition of the medical aspects of the question, a clear exposition of how the medical profession can help in this question. To do this it is necessary to bring before the profession the medical facts of addiction, and the results of medical research, investigation and observation, in both clinical and laboratory work. The medical profession needs much enlightenment in these respects, and the honest, reputable doctor wants help and counsel and instruction.

This is where the commisssioner of health can be rendering the greatest service in his power. The department has extensive laboratories with full and complete equipment, where the medical problems underlying the nature of the disease condition and the principles of treatment and cure could be worked out in scientific experimentation, research, and observation. And it has facilities for education through which the results of this work could be brought not only before the medical profession but also before the public for the benefit of the large numbers of those suffering from addiction. Yet, so far, nothing has appeared in any of the publications of the department that could offer the help, the counsel, and the advice which the medical profession so much needs and wants; and the profession has the right to expect such from the department.

True, the department has opened a clinic and a hospital for the treatment and care of addicts. The commissioner is to be commended for this step, constituting as it does the first step ever taken by the department toward a real study of the medical problems involved. Yet it is only a beginning. The department is only beginning to learn, and the same mistakes, the same errors of judgment, and the same ill results that were made by the medical practitioners outside the department are to be found in these new ventures of the department. Still, the profession has hopes that something of value may yet come from it in a medical way.

To show how important is this phase of medical attention, let me point to the stress laid upon the ten thousand addicts of a criminal nature we have in our own city of New York. The menace cannot be belittled, but this number constitutes only ten thousand out of an estimated one hundred or two hundred or even two hundred and fifty thousand addicts in the city. This number contains people in every walk of life, from the highest to lowest—honest, useful citizens, even in the highest esteem, repute, and confidence of the people—who through unfortunate circumstances, through no fault or will of their own, have developed the condition of nar-

cotic drug addiction within their own bodies. They are crying for help and for relief from their affliction, and they are looking to the medical profession for this help and relief. There is no doubt that when the medical profession does give that attention to this that it has given and gives to the questions of pneumonia or influenza or poliomyelitis, the large majority of addicts will find that relief from their affliction they pray for. When that happens, then ninety—aye, ninety-five—per cent. of the problems offered by narcotic drug addiction will be solved; and the problem of the ten thousand criminal addicts will also have been put on a fair way of solution.

What has the commissioner of health to offer in a scientific way to help and relieve this ninety or ninety-five per cent.? Just to show what a field for medical research there is in the question of narcotic drug addiction, and to point out how useful the commissioner of health could make the laboratory facilities, I wish to report one case of a baby born of an addicted mother, addicted for over two years.

I attended the birth of this child last summer. The baby was born while the mother was practically in a condition of mid withdrawal of the drug; and she showed the ordinary symptoms of that condition superimposed upon the usual nervous, excited conditions attendant upon the final stages of delivery. After birth, the baby, a well-nourished, healthy appearing female child, was very restless, crying a good deal more than usual for a child immediately after birth. As time went on, this restlessness increased, and the child developed signs and symptoms identical in character, severity, and sequence with those shown by the mother in the condition of drug need. As the restlessness increased the child began to yawn and sneeze and sniffle. It drew up its legs, as if in cramps, and moaned and cried as if in pain. Its face became pinched and ashen hued. Its pupils were widely dilated. Its chin was in a constant tremor, reminding one of the chattering and shivering of an adult during a chill. Diarrhea set in, with collapse and convulsive attacks.

This child was a narcotic drug addict from the moment of its birth. Can the commissioner of health give the results of any investigations by the department to cast any enlightenment upon this?

It would be far better for the commissioner to utilize the facilities and powers of his department along the medical lines suggested. It would lead to a definite helpful somewhere, toward the ultimate solution of the main question at issue. His present propaganda results only in increased confusion and panic, driving fear into the hearts of honest people and giving consolation and encouragement only to the underworld traffic and peddling. Information is at hand from various sources that illicit traffic in the drug is again in great activity, numerous honest addict patients having been driven to the underworld for relief by the fear and uncertainty of status of their private attending physicians. The true job of the department is to study disease conditions affecting the public health, educate the public and the profession, and get the cooperation of all who can and want to help, instead of frightening and antagonizing them.

CHRISTIAN F. J. LAASÉ, M.D.

314 EAST EIGHTEENTH STREET.

OUR LONDON LETTER

(From Our Own Correspondent)

LONDON, May 9, 1919.

The Former Constitution of the Medical Parliamentary Committee.—At an important conference of the representatives of medical and allied societies, held in London on Friday, May 2, under the chairmanship of Sir W. Watson Cheyne, the Medical Parliamentary Committee emerged from provisional into formal existence. The conference took place in the following circumstances: At an open meeting of the medical profession held last Autumn, under the presidency of Sir Henry Morris, Dr. Christopher Addison, the medical man who is at the moment President of the Local Government Board and was then at the head of the defunct Ministry of Reconstruction, proposed the constitution of a body chosen to provide in the House of Commons the considered voice of the medical profession. A provisional committee was elected with a mandate to carry out the unanimous resolution in favor of Dr. Addison's views, and the committee were instructed to place before the profession a scheme for giving effect to the resolution. It was this scheme that the Conference was summoned to discuss and approve.

The scheme consisted of the following 7 resolutions: (1) That a permanent Medical Parliamentary Committee be formed for the purpose of: (*a*) supplying information of the trend of expert opinion on health questions; (*b*) supplying early information of impending legislation to the constituent bodies; (*c*) facilitating communication between the several bodies affected by the proposed legislation; and (*d*) assisting in increasing medical representation in Parliament. (2) That the Committee consist of (*a*) a representative or representatives of any society or association of those engaged in medical or dental practice having as its objective, or taking an interest in, medico-political activity; (*b*) two representatives appointed by the nursing profession; (*c*) a representative of midwives; (*d*) a representative appointed by the Pharmaceutical Society; (*e*) a representative appointed by the British Hospitals' Association; (*f*) the editor of (i.) *The British Medical Journal*, (ii.) *The Lancet*, (iii.) *The Medical Press*, (iv.) *The Medical World*, (v) *The Medical Times;* (*g*) all medical members of Parliament; (*h*) members, not exceeding 20 per cent. of the Committee, elected by the Committee itself; (*i*) directly elected representatives of the whole medical profession, to be elected immediately the Committee's financial position warrants the necessary expenditure. (3) That the Committee meet at least twice a year. (4) That the Committee appoint an Executive Committee consisting of not more than 20 members, of whom not more than a quarter should be engaged in consultative medical practice. (5) That the Executive Committee meet at least once a month. (6) That the Executive Committee have power to appoint subcommittees. (7) That a Committee be appointed to take such steps as may be necessary to carry out the decisions of this conference.

Of these the last five were passed in unaltered form. The only alteration in the first resolution, as accepted unanimously by the conference, was

to widen the reference of the permanent Medical Parliamentary Committee, so that its collated information should be at the disposal of all bodies who had the right to seek it, and not be communicated only to medical members of Parliament, who might not be in particular need of the assistance, though they were the most important channel for the distribution to the public of medical knowledge. The only alteration in the second resolution was to add to the Committee a representative of housing and town-planning activities. The conference was therefore an unmixed triumph for the provisional Committee, who have been doing unceasing work for the past 6 months, and who found their views substantially adopted by a very varied constituency of medical and lay authorities.

But now that the permanent Medical Committee is formed still more serious efforts lie ahead of it. Though formally constituted it is without an income, while the adherence to the movement of the British Medical Association, the largest and richest union of medical men in the Kingdom, has not been promised. The view of the Association is that all which the Medical Parliamentary Committee proposes to do, is either being done, or can be better done by the Association, and if the ruling powers of the Association make this into the official attitude the new body will have to start its work without much valuable cooperation. The chances of success depend on the practical results that emerge from its early activities. If the Medical Parliamentary Committee makes good as the center for the discussion and debate of health questions between medical men and laymen, it can be sure of receiving the modest income required for its office expenses from the subscription of the bodies interested in the work; while the British Medical Association will be promptly moved to rally itself beside an institution which would place their medical members rapidly and easily in touch with auxiliary workers of all sorts and with public opinion. But if the first moves of the young Committee do not appeal to the reason or imagination as being well directed, and necessary to the maintenance of a high national standard of public health, the necessary pecuniary support will be hard to obtain. There is room here for some lay endowment. The Medical Parliamentary Committee is absolutely required, and its work is purposed to assist the public, and especially the legislation, to give proper support to health measures. Whoever found the money needed at the start would accomplish wise economy.

The High Maternal Mortality of Child Bearing.—Before the Section of Obstetrics and Gynecology of the Royal Society of Medicine, Mr. Victor Bonney, obstetric surgeon to the Middlesex Hospital, has just read an address of remarkable vigor in which the instructional methods at our medical schools in the subject of obstetrics and gynecology came in for vigorous indictment. Mr. Bonney roundly declared that child bearing to women was made unduly dangerous by the faults of domestic environment, but also by the unprogressive nature of the medical care which the women received from doctors and nurses. All Mr. Bonney's arguments were not received unchallenged, but his main test, that sepsis which was a reproach to surgery appeared to be regarded as an inevitable event in much midwifery, led to a sermon whose truth no one attempted to controvert. Whether intestinal organisms can or cannot produce puerperal septicemia, and if so to what extent, is an open question, and one which the clinical research of the future might well set itself to answer; but all must agree that obstetric examinations, manipulations and operations should be treated exactly as any surgical procedures. This is how they may be treated in institutions, but how they are not treated in the homes of the people. Often, too often, in the present condition of housing, it is impossible to secure asepsis in the home, and for this condition of things the obvious remedies are improvement in housing, and the provision of many more lying-in hospitals. But over and above these things there is needed the proper education of medical men in scientific midwifery as a branch of aseptic surgery. This was the message of a valuable debate.

King Edward's Hospital Fund for London.—The Prince of Wales presided this week for the first time at the annual meeting of the supporters of the Hospital Fund for London, which was founded by his grandfather. Never did that most popular and democratic king do a wiser stroke for keeping his memory green, and green in association with beautiful ideals, than when he decided to use his enormous personal influence with the richer sections of his friends to extract from them the necessary capital and annual support for the great charity which goes under his name. From the start King Edward's Hospital Fund for London was a success, today its large income—the receipts for 1918, the fourth year of the war, were about £206,000, say, a million dollars—is a force in hospital administration and finance. The fund is a center, also, to which hospital committees can turn for advice when contemplating progressive measures, for if those measures entail capital expense (the cost of a building, for example) they will be discussed by the authorities of the fund before any grant in aid is made.

The American Hospital in London.—Quite unnecessary secrecy prevails concerning the foundation of an American Hospital in London. We here know which of our well-known physicians, surgeons and specialists are being invited to form the British part of the staff, but, though much private information is available, no public announcement has been made yet as to the American personnel further than that, as was always understood, the junior staff will be American. The initiator of the movement is Mr. Philip Julius Franklin who retains his American citizenship, but is a Fellow of the Royal College of Surgeons of England and the holder of important posts in aural surgery and laryngology at several London hospitals.

The Death of Dr. F. J. Smith.—Dr. F. J. Smith, whose death occurred last week at the comparatively early age of 62, had just been appointed consulting physician to the London Hospital, with which institution his admirable clinical and educational work was connected for many years. Dr.

Smith, at the time of his death, was President of the Medico-legal Society and had established a high position as an authority in forensic medicine and medical jurisprudence.

The Increase of Rabies.—The increase of rabies has been undoubted in Great Britain, and since I wrote last week at least a dozen new cases have been notified, cats now being attacked. The muzzling regulations have been extended, and vigorous precautions against the smuggling of dogs into the country from the Continent are being taken. The presence of rabies over large areas of the Continent has been verified.

4. The Danger of Pestilence in Europe and the Need of an International Health Commission.—George A. Soper draws attention to the danger, not only of famine which is realized to some extent but of pestilence in Europe. War, famine, and pestilence have ever gone hand in hand, and though war has sometimes occurred, famine has never been known over a wide area without pestilence. Many factors enter into the spread of disease, but the most serious of all is the want of proper supervision over public health questions. Under circumstances of civilized and stable government, definite forms of administrative machinery exist for the prevention of disease, but a large part of Europe is bordering upon anarchy, civic and national governments are without capacity, crime is rampant and famine is not merely a menace but a reality. Cholera has already been reported at all the Baltic ports, in Germany, France, Sweden, and Spain. Typhus has been reported throughout the Balkan States, in Germany, Italy, France, Spain, Ireland, Scotland, and Russia. Plague has been reported in Spain, in the Ukraine, and in Russia. The prevention of epidemic diseases should therefore be one of the principal objects to be accomplished in the efforts which are being made to provide means where the demoralized populations of Europe may regain their industrial and commercial equilibrium. And more than this should be done. The less spectacular forms of disease should also be suppressed; tuberculosis, for example, receives very little notice among the peoples of southeastern and northern Europe, and the seriousness of infant mortality is not recognized at all. The detailed steps indicated can only be determined by a thorough investigation of the conditions. Opportunities and needs will vary in different countries, from place to place and from time to time. The first thing to be done will be to meet the present situation, the second thing to provide for the future. To do this it may be desirable to create an international health commission, whose duties would be investigating, supervisory, and coordinating. Its functions would not necessarily replace those of any existing body, but would assist and supplement agencies already exercising specific functions efficiently. Where no efficient local bodies exist, the commission might bring about their creation. The first object of such a commission would be the control of diseases of international import. The second object would be the standardization of administrative health procedures everywhere so far as local conditions would permit. Responsibility for results would rest wherever the authority was located. The author points out that a nucleus for such an organization already exists in the Office International d'Hygiene Publique, Paris. In 1903, at the international sanitary conference, which was held in Paris, an agreement was drawn up for the better management of plague, cholera, and yellow fever. This agreement was ratified in 1907. It specified, among other things, the procedures by which the epidemic diseases mentioned were to be handled, especially in the eastern countries, the object being to keep cholera and plague out of the commercial centers of Europe. An international office was established in Paris and has been functioning for eleven years; it is under the control of a committee of delegates from each of the contracting governments. The duties of this office include the receipt and notification to the several governments of facts of interest concerning public health matters and infectious diseases, particular attention being given to plague, cholera, and yellow fever. A bulletin is published each month containing a digest of laws promulgated in different countries concerning the management of transmissible diseases; information concerning the existence and progress of infectious diseases; information relating to sanitary works and measures; statistics, and bibliographical abstracts relating to the occurrence and study of disease. The scope of this bureau, however, is not sufficiently broad nor its authority and financial resources large enough, to undertake the work required at the present time. No matter what commission undertakes this work, it should have power to make investigations and reports on the existence of all forms of infectious disease and on the conditions which make for disease; it should draft and recommend the adoption of model health laws and the most suitable methods of enforcement; it should investigate the underlying principles for the prevention of disease and the promotion of health, and should announce the results of its investigations in publications to which all students and executives concerned in health work would have access. Not only in Europe are such measures necessary; it should not be left to private enterprise to stamp out yellow fever from a continent, to missionaries to control pestilences in the Near East, or to the vagaries of chance to control or stay the progress of disease. There are indications that the Red Cross may initiate an extensive health campaign throughout the world, and the Cannes conference will probably be followed by a general congress which it is expected will be held in Switzerland upon the conclusion of peace. Nevertheless, the problem is too great to be handled by even the biggest private humanitarian agency ever known. The author voices the hope that the nations will see the need and initiate the work, which ought to go hand in hand with the Red Cross program.

7. Sugar Tolerance in Cancer.—G. L. Rohdenburg, Adolph Bernhard, and Otto Krehbiel refer first of all to certain well established facts in regard to the de-

velopment of cancer: that tumor frequently follows irritation, but that in addition to this irritation there appears to be a predisposition to the disease which becomes more evident at the cancer age. They then point out that although cancer development has been attributed to faulty function of the endocrine glands, no positive evidence in support of this hypothesis has been produced. Nevertheless, they consider it possible that there may be derangement of endocrine function not demonstrable by histological or surgical technique, and they draw attention to the fact that the functional activity of some of the endocrine glands can, to some extent, be measured by the sugar tolerance test first brought into clinical use by Jacobsen in 1913. This test has been applied in a number of conditions, among which they mention diabetes, nephritis, exophthalmic goiter, pituitary disease, myxedema, and thromboangiitis obliterans. In some of these diseases typical curves of no inconsiderable value in diagnosis have been established, though, unfortunately, they are not applied clinically with the frequency they warrant. The writers have obtained values apparently constant in cancer, which they believe may ultimately prove of value in diagnosis, by the test as described. In the morning, after a night's fast, the individual is given either 100 gm. of anhydrous or 115 gm. of syrup glucose dissolved in 300 c.c. of tea or coffee without milk or sugar, care being taken that the glucose is all dissolved and that the patient takes the entire amount. Just before giving the glucose and again forty-five minutes and two hours after its ingestion, blood is withdrawn and the amount of sugar in it determined by the Lewis and Benedict method as modified by Meyers. At the same time periods the urine is quantitatively examined for sugar by Benedict's method. The epinephrin method may also be employed by giving 1 c.c. of a 1:1000 solution of epinephrin hydrochlorid subcutaneously instead of administering glucose. The cancer curve, in contrast to the curve observed in other diseases, starts with a normal blood sugar, 100 mg. per hundred c.c. of blood, rapidly rises so that forty-five minutes after the ingestion of glucose 180 or even 200 mg. per hundred c.c. are present, and two hours after the glucose is ingested, the blood sugar is as high as at forty-five minutes or higher, reaching 288 mg., and in one instance 350 mg. The percentage of blood sugar gradually falls and approximates normal in from three to four hours after ingestion of the glucose. When epinephrin is used, the curve is identical with that following the ingestion of glucose. The sugar tolerance bears no relation to the location of the tumor. In the authors' series sugar appeared in the urine in only 41 per cent. of the cases. Two cases are cited in which the test was of diagnostic value. The authors state, however, that they prefer not to theorize on the etiological significance of the phenomenon with its numerous possibilities, but content themselves in recording it so that repetition in other hands may prove or disprove its value as a diagnostic test.

12. The Production of Indol by Certain Strains of the Pfeiffer Bacillus.—Edwin O. Jordan has found that the majority of strains of the Pfeiffer bacillus form indol promptly. The paradimethylamidobenzaldehyde method was used, the medium being a standard meat infusion broth to which 5 per cent. of sheep blood was added while the broth was hot (above 90° C.), the broth then being filtered through cotton or filter paper. In all thirteen strains of the bacillus were tested. They included two strains from fatal cases of influenza—one from heart blood and one from lung tissue; seven from normal throats and one from influenza sputum. The source of the others was not known. All showed the recognized cultural and morphological characters of the bacillus. Ten produced indol abundantly in twenty-four hours. Of the three that gave negative results, two were from normal throats. Jordan points out that advantage may be taken of this character in a rough preliminary differentiation or for a "presumptive test." He states that other bacteria commonly found in the throat do not appear to be indol-formers. Zipfel and others have reported finding no evidence of indol production by the various cocci and the author has tested thirty-six different strains of green-producing and hemolytic streptococci, pneumococci, meningococci and staphylococci from the mouth, with negative results. Although diphtheria bacilli were reported by some of the earlier workers as forming indol these results have not been confirmed by later investigation. The author found that the Pfeiffer bacillus was able to grow in competition with other organisms and that the mixture yielded a good indol reaction in twenty-four hours. Throat swabs were washed directly into the broth with positive findings in about 83 per cent. Seven out of forty-eight positive cases gave a history of influenza in the fall of 1918, as did also three out of the ten negative cases. On a second testing, seven out of the ten negative cases yielded indol; in three both tonsil and nasopharynx swabs were positive. It was also found that if a peptone phosphate medium was used in which *B. coli* and other indol-producing bacteria give abundant indol, no indol was formed after inoculating with throat swabs although good growth occurred. From the fact that parallel tests from the same throat at the same time have shown indol production in the blood, but never in the peptone phosphate medium, the author thinks it probable that a hemophilic organism is responsible for the indol production from throat swabs. He points out that, assuming that the indol production in blood broth inoculated with throat swabs is due to the presence of indol-producing strains of the Pfeiffer bacillus, it would seem that this bacillus is present in approximately 80 per cent. of normal throats. By the blood agar plate cultural method the bacillus was isolated in about 40 per cent. of cases, as compared with about 80 per cent. by the indol presumptive test.

6. Lung Puncture in the Treatment of Influenzal Pneumonia.—M. Benaroya describes a method of treatment which was employed in the Royal Berks Hospital, Reading, England, in a series of 41 patients, many of whom were very seriously ill. The ages ranged from 10 months to 68 years and the patients showed all degrees of resistance. All the patients recovered with the exception of one, in whom there were septicemic complications, with prominent pericardial and endocardial signs and but few lung symptoms. The treatment described aims at determining a local accumulation of polymorphonuclear leucocytes and so stimulating phagocytosis by setting up a focus of irritation in the pneumonic areas. The author states that it is an application of the principle advocated by Kraske in the local treatment of erysipelas, and may be considered analogous to laparotomy in the ascitic variety of tuberculous peritonitis. *Technique.* The first step is to determine accurately by means of percussion and auscultation, the situation and area of the consolidated patches. A hollow needle or trocar about 2 inches long is then introduced in the direction of the patch and allowed to remain in the lung for about 30 seconds. If more than one patch is detected, it is preferable to select the largest and to neglect the others. If the base is entirely affected, as in lobar pneumonia, or several patches of considerable size are present, a second puncture may be necessary. In the present series of cases it was rarely necessary to repeat puncture, and then only for exacerbation of the morbid process. Strict asepsis is essential. As regards the seat of election, the axillary or scapula lines are, if possible, to be preferred. The author points out that as this method does not depend upon the type of organism responsible, it may be tried in every variety of pneumonia and the results in every type of case have been favorable. A steady fall of temperature is always to be expected, and in many cases it becomes normal in 24 hours. If,

within a few days after puncture, the temperature tends to rise again, a careful investigation is needed to determine the cause, and usually a new patch or some heart complication will be found. In the former case, a second puncture may be necessary; in the latter, some stimulant or heart tonic is indicated. If the puncture through injected or morbid lung tissue be made with a certain degree of rapidity, there is practically no pain. Results were most striking in early cases treated. Supporting medical treatment, of course, should not be neglected. The author also states that this method may be advanced as the preliminary basis of a new treatment of tuberculous pneumonia, especially if some means could be discovered to neutralize the toxins of Koch's bacillus *ad hoc*. Benaroya adds that he has tried various types of vaccines on an earlier and large series of cases with disappointing and illusory results. The explanation of this may lie in the pleomorphous character of the organism described by Donaldson (organism "D"), which may turn out to be the visible form of the filter-passer described by other observers.

4. Remarks on the Pathogenesis of Deficiency Diseases and on Pellagra.—P. Rondoni refers to the work of Colonel McGarrison on the changes in the organs of pigeons fed on polished rice and suffering from polyneuritis, and calls attention to the results obtained by himself several years ago when working on other deficiency diseases and published in the Italian review *Sperimentale* in the summer of 1915. He states that, after working for some years on the pathogensis of pellagra, he was unable to uphold the photodynamic theory of Raubitschek; nor could he find any precipitins in the serum of pellagra patients or demonstrate any positive complement fixation between serum of these patients and maize extracts. He did, however, find hypersensibility to the injection of maize extracts in patients suffering from pellagra and points out that Volpino has done a great deal of work on this subject. Later he adopted the view that pellagra should be regarded as a deficiency disease. Rondoni then resumes the results of experimental researches made on the maidism of guinea pigs. He refers to the facts that exclusive maize feeding rapidly brings about a pathological condition in guinea pigs, which die in about three weeks after having lost about one-third of their weight, suffering in the last period of their life from less of hair, weakness of the legs, and diarrhea; and that, when fed on cereal grains alone, these animals develop a typical scurvy-like condition with lesions of bones, bone-marrow, teeth, and blood vessels—the last occasioning a real hemorrhagic diathesis. After reviewing briefly the work of McCollum and other observers the author states that in 1913-14 he worked on the effects of maize feeding on guinea pigs, publishing his results in 1915 and 1916, his object being to show the differences between the more typical scurvy (oat feeding) and the conditions produced by feeding on maize; also between scurvy and pellagra and simple starvation. Like McGarrison, he measured the weights of various organs. He found that in all the conditions mentioned the adrenal glands were enlarged, though principally in oat-feeding and maize-eating guinea pigs, and that while the loss of body weight was only one-third, the relative weight of the adrenals was almost doubled. The spleen was reduced in weight, chiefly in the oat-eating and in the starving animals, and some evidence was found of an atrophic condition of this organ, as was the case in McGarrison's pigeons. He summarizes his histological observations thus: The organs which were the most affected in guinea pigs fed on maize were the spleen, the thyroid, and the suprarenal glands. The spleen showed sclerotic lesions with increase of elastic and fibrous tissue and reduction of lymphocytes in the folliculi. The thyroid showed, in the first days of the maize diet, hyperemia and often proliferation of alveolar epithelium, then hemorrhagic changes and later on sclerosis. He remarks that these changes, which he believes have not been observed before, may be compared with those noted by other observers in the thyroid of starving animals or of animals fed on special diets. The suprarenal glands showed hyperemia, enlargement of minute vessels, degenerative changes in the cortical cells with disappearance of the normal lipoids, perhaps slight proliferation in the cells of the outer cortical layer; the reticular fibers were thicker, and the reaction with chromium salts in the medullaries seemed to be less marked. Degenerative changes were prominent in the central nervous system. By means of Nissl's method, this observer was able to note signs of decay in the anterior horn cells of the spinal cord and in Purkinje cells of the cerebellum, and by Marchi's method frequent irregular fresh degeneration of all sorts of medullated fibers. Changes in the bone marrow were of the same nature but less in degree than those observed by Fröhlich and Holst as the result of other cereal feeding. Lesions of the liver, kidney, heart, and intestinal tract were less marked. In guinea pigs fed on oats the hemorrhagic lesions were more marked and the author is of the opinion that the hemorrhagic diathesis belongs to the typical scorbutic condition of the animals. It would appear from the author's experiments that the central nervous symptoms, fall of hair, sclerosis of spleen and thyroid are more marked in maize-fed animals. The differences between the effects of these unilateral diets and starvation are that in starvation there is no true sclerosis of organs, the disappearance of lipoids from the cortex of the adrenal glands is much more marked, and the bone-marrow conditions differ. Histologically, death from maize-eating is not death from starvation, but involves deep metabolic changes as in other real deficiency diseases and in some intoxications. In order to study the reason of the severe injury caused to the organism by maize feeding, the author attempted to supplement the maize meal or kernel with other substances. He found that the addition of casein, peptone, or animo-acids produced no definite improvement. One year later (1916) McCollum, Simmonds and Pitz showed that the maize protein contained all necessary amino-acids, but not all in the most favorable proportions, that the deficiency of maize could not be made good with casein, and that the protein factor had not the paramount importance for rats that it seemed to have for other animals. Hogan drew attention to the lack of salts in maize diet. The author points out that though he did not take into account the salts, he had already written that the protein deficiency of maize did not seem to have any great importance for guinea pigs in the development of maidism, and that Hogan's experiment of supplementing maize with casein had been made by him with the same negative results. Hogan stated that pigs were on a different basis and that here protein was the limiting factor; this had already been demonstrated by Passerini, whose experiments were unknown to the Americans. The author also made some experiments on the prevention of scurvy by supplementing the maize diet by green food and found that 10 grams a day of fresh cabbage produced a remarkable corrective action and materially lengthened the life of the animal. Thinking that possibly there might be in cabbage some lipoid-bound substance or vitamine-like principle, the author then tested the action of alcoholic extracts of cabbage with positive results, thus prolonging the life of the animals. In the light of McCollum's ideas, he believes that he partly supplemented the fat-soluble factor A, which is lacking in all cereal grains and maize and is abundant in all leaves. From the results obtained by Osborne and Mendel it would seem that the water-soluble vitamine B is absent in cabbage. An attempt to supplement maize meal with an alcoholic extract of maize bran failed, whereas, alcoholic extracts of liver prolonged the life of the animals a little. The author therefore came to the conclusion that in animal organs and in the green parts of plants there must be some alcohol-soluble body which diminishes the harmful action of maize diet on guinea pigs.

Book Reviews.

A Text-Book of Pathology. With a final section on post-mortem examinations and the methods of preserving and examining diseased tissues. By Francis Delafield, M.D., LL.D., Sometime Professor of the Practice of Medicine, College of Physicians and Surgeons, Columbia University, New York; and T. Mitchell Prudden, M.D., LL.D., Emeritus Professor of Pathology, College of Physicians and Surgeons, Columbia University, New York. Eleventh edition. Revised by Francis Carter Wood, M.D., Director of the Pathological Department, St. Luke's Hospital, New York. Director of Cancer Research, Columbia University, New York. With 15 full-page plates and 809 illustrations in the text, in black and in colors. Price $7.50. New York: William Wood and Co., 1919.

It is nearly eighteen years since the present writer prepared for these columns a notice of the sixth edition of this standard text-book of pathology. Even in this space of time the changes in the successive editions have been remarkable, but when one reviews the entire history of the work it affords an instructive commentary on the great extension in scope that the study of pathological anatomy has undergone. The first edition was a small hand-book of post-mortem examination, published in 1882 by Dr. Francis Delafield and containing less than 400 pages. The second edition, dated 1885, was the direct ancestor of the present volume, for on its title page appeared for the first time the name of Professor T. Mitchell Prudden, under whose coauthorship the work rapidly gained a preeminent position in the literature of pathology. This book covered about 600 pages and subsequent editions have grown at a rapid rate until at present nearly 1400 closely printed pages are offered to the reader. A third epoch in the development of the work is marked by the appearance of this, the eleventh, edition, which has been prepared by Professor F. C. Wood, who has added many pages of new matter and has rewritten much of the old. Owing to the wealth of knowledge that has been acquired through the growth of the related sciences of physiology, biological chemistry, and bacteriology, and the application of their special technical methods to the problems of pathology the latter has become a wonderfully complex subject instead of the simple morphological study it was a few decades ago. Accordingly much discrimination and restraint have been needed to prevent the text from exceeding the limits mechanically permissible for a treatise contained within the covers of a single binding, but despite these restrictions Professor Wood has found it possible to introduce such material relating to the pathology of function and to discuss each subject from the broad standpoint of physiological pathology. This is especially noticeable in the section on diseases of the kidney. This has been brought fully into accord with the modern investigations of renal function both normal and pathological, and the classification adopted shows the influence of the conceptions introduced by Volhard and Fahr. While the histological changes of diseased kidneys are still the same as those so carefully and accurately described by Dr. Delafield, the labels on the specimen jars have had to be altered in consequence of fuller knowledge gained through experimental work on animals and functional observations on human beings. The value of experimentation is shown also in the section on hydronephrosis, in which the modern point of view is well presented.

The very important chapter on the reproductive organs of the female has been largely rewritten and many illustrations have been added to emphasize modern views. The same thing may be said of the chapters on the bones and joints and on the nervous system, and especially to the latter extensive additions have been made. The presentations of the recent advances in the study of poliomyelitis, paresis, senile dementia, paralysis agitans, and cerebrospinal syphilis are particularly noteworthy. Owing to Dr. Wood's eminence in the field of cancer research one naturally turns with much interest to the chapter on tumors. This has been completely rewritten and forms a veritable mine of information in regard to the clinical and experimental pathology of new growths. Another chapter which shows radical revision is that on the general diseases, including the various forms of goiter and the disorders of the ductless glands.

The number of illustrations has been increased from 690 to 809, including many photomicrographs of unusual excellence. A striking addition is the colored plate showing the different types of melanotic tumors. The binding and general makeup of the volume maintain the high character which has made the volume a model for other publishers. It will undoubtedly continue to be the standard text-book for students and work of reference for the more advanced, not the less because of the valuable chapters on technique which it contains. Special comment is due to the references which are copious and timely, and are made infinitely more useful to the average reader because, instead of merely making mention of numerous articles in various foreign journals or "Ergebnisse" entirely inaccessible to physicians outside of the larger cities, citations are given largely to papers printed in English, and particularly in the more widely read journals of the United States, and for each topic the more important articles are systematically pointed out. For the readers of the present and future the book will be the same trustworthy and comprehensive guide that it was for those of former days when pathology was a comparatively simple and circumscribed science.

Estudio Clinico de la Litiasis Urinaria. Por el Dr. Angel Pulido Martin, Cirujano del Hospital de San Juan de Dios, Professor de Enfermedades de las Vias Urinarias en la Facultad de Medicina de Madrid, etc. Madrid: Imprenta del Sucesor de Enrique Teodoro, 1918.

This little work gives a clinical account of stone in the kidney, ureter, bladder, and urethra. The Hospital de San Juan de Dios is largely a urologic institute which supplies an abundance of material, and there is a detailed report of eighty-nine cases of stone of all kinds of comparatively recent date. Rather striking is the absence of reference to urologist colleagues. Guyon, evidently the author's teacher, is the chief exception. Nitze is the only authority named under cystoscopy, and a few other men are mentioned in connection with instruments or methods devised by them. Such silence in a book of this sort is at least unusual and ambiguous. The volume is but sparsely illustrated.

The Disabled Soldier. By Douglas C. McMurtrie, Director Red Cross Institute for Crippled and Disabled Men, Federation of Associations for Cripples, Editor *American Journal of Care for Cripples*. With an Introduction by Jeremiah Milbank, Vice-Chairman Committee of Direction Red Cross Institute for Crippled and Disabled Men. Price, $2. New York: The Macmillan Co., 1919.

No one knows better than Mr. McMurtrie the needs of the disabled soldier, sailor, and marine from the standpoint of rehabilitation, and no one, at any rate, on this side of the Atlantic, has done more to aid in the reconstruction physically and mentally of those injured in the war. Not only, however, does Mr. McMurtrie know his subject thoroughly, but he is able to express his views in terse, vigorous English. He is indeed a writer of no mean ability and brings to his task a healthy enthusiasm. Endowed with these attributes he has written a really good book on rehabilitation and one which can be read with the certainty that valuable information will be gained therefrom. The book is excellently illustrated, and in all respects is well worthy of its subject, than which there can be no higher praise.

Indigenous Drugs of India. Their Scientific Cultivation and Manufacture, with Suggestions for the Development of New Industries. By J. C. Ghosh, B.Sc. Manchester, F.C.S., Pharmaceutical Chemist, Government Medical Stores Department. Price, One Shilling. Calcutta: Butterworth & Co., 1918.

The indigenous drugs of India are considered in this little volume and it is pointed out that the native vegetable drugs should have in the future a great vogue. The war has not only impeded the manufacture of synthetic remedies, but has focussed attention upon vegetable preparations which had fallen into disrepute. Dr. Ghosh's book, which is written with the view of creating an interest for the wider adoption and use of indigenous Indian drugs on scientific lines, is very apropos and should have the desired effect.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Thirteenth Annual Meeting, Held in Syracuse, May 5, 6, 7, and 8, 1919.

(Special Report to the MEDICAL RECORD.)

SECTION ON OBSTETRICS AND GYNECOLOGY.

First Day—Tuesday, May 6.

DR. H. DAWSON FURNISS OF NEW YORK IN THE CHAIR.

THIS was a joint meeting with Section on Surgery, for a Symposium on Urology.

The Diagnosis of Renal Colic.—Dr. GEORGE WILLIAM STARK of Syracuse presented this paper, giving as his reason for selecting this subject the fact that renal colic or renal pain was too often overlooked in the human body. He stated that renal colic was caused by an obstruction in the urinary tract from the kidney to the bladder, accompanied by more or less pain. The most important causes were: Strictures of the ureters, kinks in the ureters, stones obstructing the ureters, tying off of the ureters, and pressure from without, such as tumors. Occasionally the ureter might be caught by an adhesion external to the ureter. The disease conditions that were usually confused with renal colic were appendicitis, diseased adnexa, gallbladder disease, duodenal ulcer, peritoneal adhesions, neurasthenia, pancreatic diseases, and lumbago. In appendicitis the rigidity and leucocytosis were more marked; in gallbladder disease, jaundice and turbid bile in the Einhorn bucket assisted in the differentiation; in duodenal ulcer blood on the string or blood in Einhorn's bucket and the *x*-ray assisted in making the distinction, and in pelvic disease satisfactory pelvic examination should help clear up the diagnosis. Any case with pain in either side that showed pus in the urine, or frequency of urination, or at some time in the course of the disease a history of a typical attack, should be investigated by a urologist. The severity, the location, or the radiation of the pain did not in any way distinguish the pathology of the kidney or ureter. It might vary from slight discomfort to veritable agony which could not be controlled by morphia. The duration of the pain might vary from a few minutes to hours, the most common type being that which began in the loin and radiated downward along the course of the ureter toward the bladder, to the ilium, sometimes to the leg, and at times to ovary or testicle. As to whether an obscure pain in the abdomen or back was caused by obstruction in the ureter or other pathology in the abdomen, a very accurate diagnosis could be made by means of cystoscopy, ureteral catheter, pyelography, *x*-ray, and functional test. The writer believed that most cases of pyelitis in which the infection had not extended into the substance of the kidney would get well. Strictures could be remedied, and the ptosis of the kidney, with kinks in the ureter, should be symptomatically cured by dilatation, drainage, and irrigation, plus a belt, and the results were uniformly more successful than those obtained by surgery, although the dilatation might have to be repeated. The writer reported his results in the treatment of a series of 146 cases, the majority of whom had been seeking aid in the profession for from four months to nine years, and yet 96 per cent. had been cured by lavage of the kidney pelvis and dilatation of the ureter. Only 11 per cent. had had to resort to surgery; ½ per cent. were doubtful, and 2½ per cent. were not cured.

Dr. F. W. ZIMMER of Rochester reported a case of stone in the pelvis of the kidney upon which he was requested to operate about one and one-half years ago. The time was set for the operation. Just before the operation he was shown the *x*-ray plate of the right kidney, which showed a stone the size of a green olive in the right of a considerably enlarged kidney. The operation was performed, the kidney with the stone removed, the ureter tied with fine chromic gut and dropped, and a rubber drain was placed and removed after five days. The incision was then practically healed. Some three months later the patient's physician informed him that she was again very ill with pain in the left renal region. The *x*-ray showed two or more large stones in the pelvis of the left kidney. This kidney was exposed and the stones removed the largest being the size of a small egg. The incision in the pelvis of the kidney was closed with fine chromic gut and a pad of fat sewed over the line of suture. There was practically complete anuria for seventy-two hours, after which the urine increased slowly in amount. The patient was very ill for three weeks. Six months after the last operation the patient had fully recovered and was still perfectly well and doing her own housework.

The Recognition and Management of Bladder Symptoms in Spinal Cord Disease.—Dr. ERNEST M. WATSON of Buffalo presented this communication, which was based on his experience in the urological service of the Buffalo General Hospital. He stated that there was definite evidence that sympathetic efferent fibers from all the nerves between the first thoracic and second, third, and sometimes fourth lumbar nerves were concerned in the innervation of the bladder and urethra. In addition, the sacral autonomics through their postganglionic fibers with their motor cells lying in the vesical plexus near the surface of the muscles they supplied were intimately associated with above. In the cord proper definite branches from the first, second, and third sacral nerves went directly to the vesical plexus, while along the paths in the cord were in the posterior portion the lateral columns near the pyramidal tracts which were believed to be the path of impulses from the higher cortical centers. From this multiplicity of innervation we could appreciate the difficulty in attempting to interpret the neuropathology of bladder disturbances. After discussing the mechanics of bladder tension and urination, he stated that any lesion which interfered with the integrity of the reflex arc might give one or more of the socalled group of bladder symptoms. Of the essential bladder symptoms encountered in spinal cord disease, incontinence and, less frequently, retention were the two predominating. The incontinence might be a true incontinence due to relaxed atonic condition of the musculature about the outlet of the bladder, including the internal and vesical sphincter, the intrinsic involuntary muscles of the posterior urethra, and probably also the external sphincter. In this type the bladder was usually of small capacity and there was usually little or no residual urine present. The other form might be of the socalled paradoxical variety in which there was really a retention present and the incontinence was the overflow of a greatly distended bladder. In this latter instance the bladder capacity might be normal, but was usually considerably increased. Before the onset of the above rather characteristic but late symptoms there was usually noticed a hesitancy or difficulty in starting the stream which frequently antedated the more serious complaint for months or years. Another of the early disturbances might be an increased frequency or in some cases, while the bladder was undergoing the process of gradual dilatation, long intervals between voidings. From the atonic state of the vesical musculature and from the not infrequent occurrence of varying amounts of residual urine the condition was one which was very prone to be complicated by infection. When this occurred there might be various degrees of burning, painful burning, and general dysuria. The early recognition of the vesical symptoms in disease of the spinal cord was of paramount importance, as much could be accomplished for these individuals under a careful routine of functional punctuality and rational therapy. In all cases in which there might be question of spinal involvement the deep and superficial reflexes should be carefully studied. In order to determine their exact status several examinations might be necessary. The pupillary reflex, the action of the biceps triceps, and periosteal radials of the upper extremity; the abdominal and cremasteric reflexes, the knee kicks, plantar responses, and ankle jerk were all of much value. The Romberg test should also be made. In the rectal examination one frequetly encountered a very definitely relaxed external sphincter, which was a very suggestive finding. The cystoscopic findings might also add much in the way of positive evidence. The study of a spinal case was not complete without the data furnished by the exami-

nation of the spinal fluid, which should include a spinal fluid pressure, cell count, globulin determination, the Wassermann and the colloidal gold tests. The management of the spinal bladder called for a well-outlined plan of procedure covering, in many cases, a considerable period of time. The first step should be to determine the presence or absence of infection, as evidenced by the finding of pus and organisms in the microscopic examination of the third glass of voided urine or of a catheter specimen. Infected cases should be given urotropin. Individuals with residual urine of over 100 c.c. should have systematic catheterization every two days, and the more advanced cases every day for a time. This should be followed by bladder lavage with nitrate of silver solution, ten drops of a 10 per cent. solution to a quart of water. In addition he had found it of distinct advantage to leave in the bladder a half ounce of 10 per cent. argyrol solution. Individuals who still had some degree of tonicity to the musculature about the bladder orifice might be given periodic dilatation of the posterior urethra once or twice a week. Certain aids might be given by the patient himself. From the beginning he should drink copiously of water. In addition he should be instructed to inaugurate a certain routine of voiding and passing urine at definite intervals, usually not longer than two hours apart. A further effort in the way of gaining voluntary control might be made by practising stopping and starting the stream. By far the most common lesion of the spinal cord one found giving early bladder symptoms was tabes dorsalis. In a recent detailed study of the course of bladder symptoms in tabetics under intraspinal therapy using mercurialized serum, it was found that of the cases having residual serum everyone showed a marked decrease in the amount, and in over 40 per cent. no residual was obtained after several treatments in repeated examinations.

Dr. Harry E. Wheelock of Jamestown said it was his privilege recently to observe seventeen cases of gunshot wounds of the spinal cord, involving almost every segment, at the Walter Reed Hospital. They were usually in bad shape and described as paradoxical incontinence. Since these cases had retention with overflow and residual urine, it was thought that blood urea estimation would be interesting and perhaps aid in determining whether there was impairment of the kidneys by back pressure or infection. The striking finding of 60 to 120 mg. of urea nitrogen per 100 c.c. was found with corresponding pathalein function. This led to the belief that possibly there was some mechanical injury to the kidney, but an autopsy in a case dying of asthenia revealed normal kidneys. A month later all the bloods were examined again and the urea nitrogen was normal. The best explanation of this they could think of was that the concentration of blood solids was increased due to dehydration. No matter where the cord was injured, the bladder symptoms seemed to be strikingly similar. It was the picture described so frequently in spinal disease, namely, dilatation of the posterior urethra, relaxation of the internal sphincter, atrophy of the trigone, patulous and fixed ureteral orifices, and irregular trabeculations. In addition to the method of management mentioned by Dr. Watson, they found that stimulation of the peripheral nerves produced favorable results. Massage over the bladder as well as massage of the prostate seemed to be beneficial.

Second Day—Wednesday, May 7.

Dr. H. Dawson Furniss of New York in the Chair.

Symposium on Diseases of the Uterus: Physiology and Anatomy of Endometrium Changes.—Dr. Lawrence Watson Strong of New York City presented this communication, in which he described the uterine mucosa in the proliferative and secretory stages. He stated that the secretion was mucous and that the presence of glycogen and trypsin had not been conclusively proven. He reviewed the theories of menstruation and cited the objections to them. In discussing the histology, he explained the variations in size and form of the uterine glands and stated that if the stroma was scanty the wall of the gland would buckle as it grew in length, thus producing the serrated form characteristic of the premenstrum. This might be absent when the stroma was abundant so that it was not diagnostic of the secretory stage. The gland might be dilated from accumulation of secretion if its lumen was obstructed; thus were produced variations in size and small cysts, which were not to be looked upon as pathognomonic of any specific condition. The number of glands was absolutely dependent upon the number in the basal layer, and these did not increase with the growth of the functional layer. This controverted the old idea of glandular endometritis. No mucosas from uteri removed by hysterectomy showed mixtures of the proliferating and secretory stages. The significance of various cell types was discussed and the amount of desquammation at menstruation. In discussing the pathology, he stated that endometritis showed only the same exudative destructive or reparative processes as were characteristic of inflammation in general, and it was only when these were present that a diagnosis of endometritis could be made. All the glandular variations and stromal changes formerly described as endometritis were now recognized as cyclic changes. A corollary of this description of endometritis was that it was practically always bacterial in origin. So it was chiefly puerperal and gonorrheal. Etiologically endometritis might be divided into bacteria, toxic, mechanical, and thermal. All these produced identical appearances, varying only in degree. The distinction betwen acute and chronic forms of endometritis from a histological point of view depended upon the different elements of the exudate and the effect of a chronic irritant upon the mixed elements of the tissue. Hyperplasia was an exaggeration of the normal and was not limited to the proliferative stage. Its histological appearances merged insensibly into neoplasms. The writer discussed hypoplasia, atrophy, and metaplasia, and coordinated the physiological, histological, and pathological data. He said that the uterine mucosa was resistant to pathological change. Inflammation did not destroy the menstrual cycle. Endometritis was not a frequent cause of menstrual disorders. Hyperplasia did not destroy the menstrual cycle.

The Distribution of Adenomyomata Containing Uterine Mucosa.—Dr. Thomas S. Cullen of Baltimore presented this paper, in which he stated that adenomyomata of the uterus might be found in the uterine horn, the round ligament, the utero-sacral ligament, the recto-vaginal spectum, and the umbilicus. The adenomyomata considered consisted of a matrix of non-striped muscle and fibrous tissue. Sometimes the fibrous tissue predominated, whereas in other tumors the muscular elements were more abundant. Scattered throughout this matrix or groundwork were isolated groups of glands, sometimes lying in direct contact with the muscle but usually in a characteristic stroma. The glands resembled in every particular those found lining the body of the uterus. In short, the adenomyoma resembled a diffuse myoma with islands of uterine mucosa scattered throughout it. Adenomyomata of the body of the uterus might be limited to the anterior or posterior walls of the uterus or form a mantle or zone just outside the uterine mucosa. When the uterus was cut open it was noticed that the anterior or posterior walls of both were thickened. This increase in thickness was due to a coarse striated condition of the muscle directly beneath the uterine mucosa. The histological picture in a typical case of adenomyomata was characteristic. It was not difficult to figure out to what symptoms an adenomyoma of the uterus would usually give rise. As a rule, we should have no intramenstrual discharge, since the mucosa lining the uterine cavity was perfectly normal. With the advent of a menstrual period, however, the patient would not only lose her quota of blood, but this would be greatly increased by the flow coming from the large areas of mucosa which were scattered throughout the diffuse myomatous growth. There would be a great deal of pain in the uterus, due primarily to the swelling of the mucosa which was scattered throughout the uterine walls. On bimanual examination one found a uterus that might be normal in size or it might be two or more times its normal size and slightly nodular. The introduction of a sound usually showed a normal cavity and on curettage normal mucosa was invariably found. From the clinical findings one could often make a fairly accurate diagnosis of adenomyoma. The removal of such a uterus was usually clearly indicated. In addition to diffuse adenomyomata of the uterus one found another variety,

namely, small adenomyomatous nodules in one or both uterine horns. These could hardly be looked upon as a clinical entity, but rather as a part of the end results of a mild inflammatory process. Some adenomyomata of the round ligaments could be removed very readily, while others were so intimately blended with the surrounding structures that they must be literally cut away. On histological examination they were found to be made up of non-striped muscle, fibrous tissue, and the characteristic uterine glands. Adenomyomata of the utero-ovarian ligament were naturally of little clinical significance and would only be recognized in the laboratory. The writer had reported one case. He knew of only one case of uterosacral ligament; his colleague, Dr. W. W. Russel, had also removed a nodule from the uterosacral ligament that showed the typical adenomatous picture. Dr. Cullen laid particular emphasis on adenomyomata of the rectovaginal septum. These, if overlooked, would in time cause the patient to become a chronic invalid, and in some instances would undoubtedly lead to her death. They usually started just behind the cervix, and on bimanual examination one could feel in this region a small, somewhat movable, nodule scarcely over a centimeter in diameter. As the growth increased in size it might involve the adjacent anterior rectal wall, the broad ligament, encircle the ureters, or envelop the pelvic nerves; it might push through into the posterior vaginal vault forming definite and well formed vaginal polypi, and, finally, it might break through into the vagina. In this type of adenomata the patient complained of much pain just before and at the beginning of the period, especially at the time of defecation. On bimanual examination a small nodule was felt directly behind the cervix. In the early stages it was possible to open up the vaginal vault and remove the tumor. As a rule, it involved the posterior part of the cervix and could not be shelled out. Where it was 1 cm. or more in diameter the abdomen should be opened the ureters isolated, and the uterus with a cuff of the vaginal mucosa removed. In cases in which the growth was widespread a preliminary permanent colostomy was imperative. Later the pelvic structures could be removed *en bloc*. Adenomyomata of the umbilicus were always small. In the writer's book an entire chapter was devoted to this subject. Removal of the umbilicus was all that was essential in these cases.

Cautery Methods in the Treatment of Uterine Cancer.—Dr. Victor Leo Zimmermann of Brooklyn presented this communication, in which he said that he should assiduously try to avoid the pitfalls which in the past had ensnared cautery and heat enthusiasts, and had even threatened to discredit them. He had had quite a good deal of experience in the treatment of uterine cancer with the cautery, beginning his apprenticeship under the great master John Byrne, but he had neither reached the stage of perfection in its handling nor acquired that faith in its infallibility which made him insensible to its shortcomings, nor was he blind to the value of other agents. In adenocarcinoma, beginning in the cervical canal, with general enlargement of the portio vaginalis, at the stage when by far the greatest number of cases were seen by the gynecologist he believed we would have a larger percentage of cures by the original high cautery amputation of Byrne than by any form of extirpation, and with a much reduced primary mortality. He had no patience with those who referred to the work of Byrne as done for the relief of hopeless cancer. While he did relieve symptoms and prolong life in comparative comfort for such advanced cases as came to him, his claim to recognition was based upon a much more important achievement, that of devising a distinct curative galvanocautery operation for the early case of cancer of the cervix. Byrne laid great stress upon the necessity of turning the heat on gradually after the knife had been applied cold. The incision was then carried through the mucous membrane around the cervix, care being taken not to make traction on the cervix until the knife had penetrated the submucous structures. This was to lessen the danger of injuring the bladder and rectum. It was a mistake to make the incision and attempt to dissect off the bladder as in ordinary vaginal hysterectomy, as this caused free bleeding which defeated the object of the operation. Care must be taken to keep the knife at a dull cherry-red heat; if the knife was too hot free bleeding would take place. As soon as the submucous tissue of the cervix was reached, gradual and firm traction was made upon the tenaculum in the canal, at the same time directing the point of the knife inward toward the internal os. In this way, by slowly pressing the cherry-red knife inward, searing well the cut surface and at the same time making firm and steady traction upon the grasping forceps, it was possible to complete the amputation well above the level of the internal os, leaving only a part of the body and fundus. The resulting cavern should be gone over again with the dome-shaped cautery until it was thoroughly charred and roasted. This was a very important point. The fact that this operation was devoid of hemorrhage and shock made it a particularly good choice for the woman who was weakened by previous blood losses, for the woman of advanced years, for those with thick abdominal walls and especially for those who on account of nephritis or cardiovascular disease were poor risks, and on whom a major operation was not advisable. Consent was easily obtained, convalescence was easy, the stay in the hospital was short, and mortality and morbidity practically nil. The objections to this operation were that the contraction of the scar following the burning away of the cervix might result in a stenosis causing dysmenorrhea or hematometra in women not beyond the menopause. It also had the disadvantage of destroying the cervix removed for microscopical examination. The writer of the paper reviewed the modifications of the Byrne operation. In speaking of the Percy method, he stated that it was not considered today as safe and simple a procedure as it was a few years back. On account of its apparent harmlessness and ease of application, every practitioner who had a case of cancer of the uterus purchased an outfit and applied the treatment. Many had never handled a cautery before, and operative deaths and troublesome fistulae followed as a matter of course. But all credit was due to Percy for putting cautery methods on a more scientific basis, teaching us to guide the vaginal work from the abdominal side, perfecting the water cooling specula, and encouraging hope of relief for patients formerly abandoned in despair.

Chronic Appendicitis; a Study of Postoperative End Results.—Dr. Edwin MacDonald Stanton of Schenectady read this paper, which was based on the analysis of the clinical histories of 110 patients operated on by him under a preoperative diagnosis of chronic appendicitis and definitely cured as proven by the end results records over periods of from one to ten years following their operations. Considerable confirmatory data had been obtained from the histories of an approximately equal number of patients operated for acute appendicitis but who after operation found themselves cured of a long standing tendency to attacks of so-called indigestion. A third group of histories studied was composed of cases not demonstrably benefited by appendectomies performed by the writer and by other surgeons. The point that he emphasized particularly was that practically without exception the cured cases in his series had presented a definite and constant group of symptoms. The symptoms which according to his experience had been characteristic of chronic appendicitis had been equally conspicuous by their absence from the histories of the uncured cases. He also emphasized the relationship of the characteristic symptoms of so-called chronic appendicitis to the well known symptoms of the acute attack. Taking the 110 cured patients as a group the striking fact was that 108 complained of attacks of epigastric or mid-abdominal pain or distress; 95 stated that they had one or more attacks in which the primary pain and nausea were also accompanied by pain or soreness in the right lower quadrant, a fact which aided materially in the diagnosis, but even in these patients the subjective symptoms directly referable to the region of the appendix constituted but a minor part of the total discomfort. On the other hand, their uncured patients almost without exception complained of pain in the right lower quadrant as their chief symptom. It was all together probable that the symptoms of appendiceal indigestion were caused by the same abnormal condition which was the predominating factor at the onset of the acute attack, namely, an obstruction interfering with the free

drainage of the appendix, and that as long as the lesion remained a mechanical one the pain or discomfort was referred to the mid-abdominal region. The uncured patient had for the most part fallen into two sharply defined groups. The larger group was typically represented by the young woman who haunted the surgeon's office complaining of right inguinal pain usually associated with varying degrees of constipation. In these cases a carefully taken history failed to reveal the two cardinal symptoms of appendicitis, namely, the cramp-like diffuse mid-abdominal pain and nausea. The great majority of the patients at operation presented a normal appendix and an enlarged movable cecum of the type described by Wilms. Dr. Stanton said that when he first reviewed his end results in appendectomy for chronic appendicitis he found errors of diagnosis in 36 per cent.; during the past eight years 86 per cent. of the patients he had operated on for chronic appendicitis had been definitely cured by the operation. In his experience chronic appendicitis had proven to be a rather sharply defined disease in which the symptoms might be recognized by the fact that they reproduced in miniature the first symptoms of the acute attack. The disease differed from acute appendicitis by the fact that the obstruction was incomplete or because it was habitually relieved before the acute inflammatory stage developed. These symptoms, characteristic of chronic appendicitis, might be present in gastric or duodenal ulcer, in gall-bladder disease, in chronic constipation and in enteroptosis. The points of differentiation were mentioned.

Dr. Gilbert David Gregor of Watertown said the term chronic appendicitis had become familiar not only to the profession but to the general public. Patients would even present themselves at the surgeon's office with a self-made diagnosis of appendicitis and demand operation, and he had even suspected physicians of sending their troublesome patients to the unwary surgeon in the hope that an appendectomy would be done and then the subsequent unsatisfactory condition of the patient would be attributed to an unsuccessful operation rather than to fault in the medical treatment. Dr. Stanton had well said that the pathological findings and the clinical symptoms did not correspond. This discrepancy was due to the fact that the appendix was a vestigeal organ and that retrograde involutionary changes were often mistaken for pathological conditions. He was fully in accord with Dr. Stanton when he demanded a distinct syndrome before he made the diagnosis of chronic appendicitis. Pain in the lower right quadrant did not constitute chronic appendicitis. For years he had told his patients that if there was no nausea there was no chronic appendicitis. The speaker also referred to the relationship between chronic appendicitis and gastric and duodenal ulcer. He believed that a chronic appendicitis was not only responsible for a type of dyspepsia resembling the symptoms of gastric and duodenal ulcer, but he believed that it was also responsible for the ulcer itself, and an ulcer that not infrequently persisted after the removal of the appendix. With the sclerosing appendix, the neurotic female, and the appendiceal hypochondriac a surgeon was in constant danger of doing an unnecessary operation, but Dr. Stanton had given a good working rule, "Not to operate unless we had the characteristic syndrome."

A Clinical Study of Preoperative and Postoperative Blood Pressure as an Aid to the Differentiation of Shock Hemorrhage.—Dr. John Osborn Polak of Brooklyn made this presentation. He concluded that there was a constant rise of five to fifteen points in the hemoglobin readings following anesthesia, when such anesthesia occupied more than 30 minutes. Consequently allowance must be made for this rise in using hemoglobin estimations as a diagnostic sign in internal bleeding. The erythrocyte count was also increased but its variation from the preoperative was so slight that it did not warrant any conclusions. In the majority of cases there was a moderate fall in both systolic and diastolic blood pressure following ether anesthesia. The blood pressure returned to the preoperative reading in 12 to 48 hours following anesthesia. The inhalation of oxygen after the withdrawal of ether vapor diminished this fall in blood pressure but was only transient in its effect. In cases of shock, especially where there had been much blood loss during the operation, the fall in blood pressure was greater than after long operation without blood loss, dropping from 10 to 50 millimeters. The pulse pressure was a better index of hemorrhage or cardiac failure than the systolic pressure. There was a constant rise in the leucocyte count in hemorrhage, while the leucocytes fell in shock. When the preoperative kidney function was low the pulse pressure must be relatively high to compensate for the deficiency, as it did no good to add saline by skin or bowel or infusion unless there was sufficient cardiac strength to take it up and carry it along.

Repair of Complete Perineal Lacerations.—Dr. Albert Scott Harden of Newark, N. J., gave a motion picture demonstration of the operative procedure in perineal lacerations.

Third Day—Thursday, May 8.

Dr. Thomas P. Farmer of Syracuse in the Chair.

Influenza as a Complication of Pregnancy.—Dr. William T. Getman of Buffalo reviewed the history and progress of former pandemics of influenza. He stated that it had not been shown either in previous epidemics or in the present one that the pregnant woman was more susceptible to influenza than the non-pregnant or males, but it had been shown that the present epidemic had been particularly fatal to the pregnant. This was largely due to the marked respiratory type of the infection, the frequency of pneumonia, and the high death rate of these pneumonias. In a series of 74 pregnant women in his own obstetrical wards of the Buffalo General Hospital and of cases reported by friends, 30 had influenza of either a mild or severe type. None of those having the mild type miscarried, but 16.6 of those having the severe type did. The mortality was highest and miscarriage most frequent from the sixth to the ninth month. He thought the exceedingly high mortality attributed to influenza among all classes, pregnant and non-pregnant, was erroneous, and that it should be attributed to bronchopneumonia, probably with a streptococcus (hemolytic and non-hemolytic) type of infection. There was a small number of influenza cases in newborn babies, to which he added three. In his service at the Buffalo General Hospital but one patient contracted the disease; two internes and four nurses also were affected. He thought their freedom from the infection was due to the wearing of gauze masks and the instillation of freshly prepared 10 per cent. argyrol solution into the nostrils of physicians, nurses, and patients twice a day. The women aborting or delivering themselves did not seem to have any harder time than those that had not had influenza, though in two instances the labor was protracted without cause. They had decided that it was better not to induce abortion of labor in influenza cases. As to the cause of abortion or premature labor in these cases, whether due to an infection of the endometrium and placenta, to death of the fetus from the same disease, or to general overwhelming toxemia, he had been unable to form an opinion. There seemed to be no routine treatment. Fresh air, digitalis in all its forms, small doses of morphine to allay coughing, and larger doses to prevent premature labor and for labor pains, were the remedies used. Atropine was used for the edema of the lungs but seemed to have no effect. As to what could be done to prevent such a heavy loss of life in the future nothing had been offered in the way of treatment, so they must try to prevent the pregnant woman from contracting the disease. They must be advised against attending public gatherings, riding in street cars, seeing friends and relatives with even a suspicion of a cold, and must use 10 per cent. argyrol twice daily in the nostrils. One well known physician had given it as his opinion that women should avoid pregnancy for the next two years, or until the subsidence of the present type of influenza.

Dr. Edward Parker Davis of Philadelphia stated that when Peary's party were going over the ice in the Arctic region during a southwest wind they were seized with influenza, so it seemed that cold did not destroy the bacillus of influenza. In Philadelphia they lost 11,000 citizens and probably had both the highest

mortality and the highest morbidity of any large city in the United States. In explanation of the high mortality not only among pregnant women but among the general population he felt that it might be attributed to the war. The entire population had been subjected to unusual stress and strain. The women had been working hard in Red Cross work, the pregnant women as well as others, and the men had not taken their usual vacations, so there was a general lowering of the resistance of the people. Among pregnant women there were two types of influenza, one which was comparatively mild and one that was deadly. He thought that what made the difference was the resisting power of the individual. Some patients if put to bed, given a purge, fed simple food, and prevented from coughing by atropine and codeine had a comparatively mild attack. On the other hand, a patient who was half-starved and showed no resisting power whatever, developed a massive bronchopneumonia. He saw no typical pneumonias in the whole series. The mechanical conditions of advanced pregnancy made it difficult to treat these patients. He saw no reason for placing any confidence in serum either as a prophylactic or curative agent and no especial reason for the use of any one drug. There was striking value in the absolute policing of the patient and in the treatment outlined above. In the presence of acute infection labor should not be induced because it opened up new avenues for the absorption of a new infection. Another point that might be noted was in reference to pulmonary embolism. After having had such a case he had made a study of this subject, and as nearly as he could find out the cause for this disaster was a preexisting pulmonary infection. He traced the cause of the embolism in his case to an influenza sometime before. Any pulmonary disorder exposed the patient to the danger of thrombosis and embolism, if any great disturbance occurred in the course of labor.

Dr. E. W. Belknap of Syracuse said he had had eight cases of influenza in pregnant women; five developed pneumonia and two of the five died. Two of these cases aborted and one went to term. The pneumonias were characterized by edema of the lungs. One of the pneumonia patients was doing fairly well at nine o'clock in the morning, she went into labor at four in the afternoon, was delivered at nine, and died at 11 o'clock that evening. She had an acute suffocative double bronchopneumonia. He had used the same treatment for his patients as was advised by Dr. Davis. Digitalis and strychnine did no good but he had heard several doctors say that whiskey and brandy were more effective.

Obstetric Surgery.—Dr. Edward Park Davis of Philadelphia presented this communication, in which he stated that the obstetrician in his effort to preserve life was contending against the most important enemies which confronted the surgeon, namely, hemorrhage, shock and infection. The obstetrician of today could not content himself with extracting the child and closing lacerations of the perineum but should investigate the condition of the birth canal, close all lacerations, and take additional precautions against shock and infection. After a forceps delivery under competent anesthesia reasonable time was given for the closing of the sinuses of the uterine wall, and then the placenta was expressed by Credé's method or manually. The patient was kept under anesthesia following the removal of the placental membranes, cord, and blood clots. The uterus was then irrigated with one per cent. lysol, or a weak iodine solution, or physiological saline solution, and packed with 10 per cent. iodoform gauze. Then all the cervical and perineal lacerations were closed. The obstetrician might elect immediate closure or he might wait a day, just as the surgeon might use his own judgment in selecting the time for the repair of lacerated or bruised tissues. The indications for delivery by abdominal and vaginal section had been extended in recent years. It was now recognized that abdominal section was the suitable procedure for fetal impaction with threatened rupture of the uterus which might make vaginal delivery in the highest degree unsafe. In some cases when the fetus was dead its vicious position was accompanied by septic infection and then the risk to the mother of vaginal manipulation was greatly increased and in desperate cases it might be necessary to sacrifice the uterus to save the life of the mother, and this could only be done by abdominal section. Ectopic gestation was recognized as a clear indication for abdominal section. Obviously in the early months of pregnancy the low implantation of the impregnated ovum required immediate emptying of the uterus with precautions against hemorrhage and infection. Where the viability of the child could not be ignored, if the placenta was laterally, marginally, or partially attached, mother and child might receive adequate care if the membranes were ruptured and the uterus made to press the presenting fetal part firmly against the placenta. If this pressure was maintained through labor and post partum hemorrhage could be anticipated and prevented, mother and child would do well with these simple precautions. When the placenta was centrally located or occluded the os the indication was for prompt delivery by abdominal section as soon after the hemorrhage as possible. An accidental separation of a normally implanted placenta was a condition analogous to that of a ruptured tubal gestation and here abdominal delivery afforded the only prompt and secure method of rescuing the mother from insidious danger. In complicated labor today embryotomy was justified obviously in the presence of a dead fetis in a genital tract too small to permit of its spontaneous delivery but large enough to warrant removal if dismembered. In a patient whose child was dead or dying a vaginal delivery would be difficult and dangerous, and if there was a possibility that sepsis complicated the situation the solution of the problem depended on whether the woman had living children and whether she and her husband consented to sterilization. Sometimes when the anatomical elements for a successful labor were present the normal physiological elements were absent, there being a pathological condition of the uterine muscle, which made recourse to surgery necessary. He had long ago abandoned abdominal section for toxic patients suffering from convulsions, except in a vigorous primipara with a shortened and undilated cervix who did not respond to eliminative treatment. There was a distinct field for elective abdominal section in the toxemia of pregnancy. If a pregnant woman had an infected appendix it should be removed as soon as the diagnosis was made, the earlier the better. Whether an infected gallbladder in a pregnant woman should be drained was not yet established, but certainly during pregnancy or the puerperal state surgical treatment of cholecystitis was often indicated and successfully carried out. In some cases of pyelitis of pregnancy drainage of the kidney by incision was followed by good results. In rupture of the uterus and pathological conditions of the pelvis which rendered vaginal delivery impossible or unsafe, abdominal section was indicated. The surgeon and gynecologist would assert that when the abdomen had to be invaded in pregnancy or labor the obstetrician should summon them. Conditions were sometimes such that this was impossible, and the important part of a surgical procedure was not its performance but an accurate diagnosis of the condition. Here the surgeon and gynecologist were not competent to decide properly upon obstetric procedures. The general practitioner might ask in what capacity he entered the field of obstetric surgery. The general practitioner of medicine did not always recognize that he had within his grasp the most important, attractive, and lucrative specialty in medical science, that of diagnosis. No man should undertake obstetric diagnosis who could not diagnosticate the presence or absence of engagement of presenting parts.

Dr. F. W. Zimmer of Rochester reported several cases of appendicitis during pregnancy which were operated on and the patients recovered; in one instance the patient did not recover. He also described a case of intestinal obstruction during pregnancy operated on through a McBurney gridiron incision on the right side, but failing to find the obstruction this incision was closed and a similar one made on the left side, where a torsion of the sigmoid was found. This woman made an uneventful recovery and did not abort.

Dr. E. A. Parker of Brooklyn said he was not

among the fortunate obstetricians who delivered the majority of their cases without lacerations and he often incised the perineum to prevent a more serious tear. A few years ago they began examining every woman at the time of her discharge and they found that the cervix either on the anterior or posterior wall almost invariably showed some laceration. It was his custom to repair these tears at once if they were extensive, but he usually did an intermediary repair. He thought that operative delivery in eclampsia had not been altogether abandoned, and cited an instance in which he had tried Dr. McPherson's conservative plan, but there was a recurrence of the convulsions and he did a cesarean section.

Dr. DAVIS, in closing, said the paper was written for the purpose of putting obstetrics on the proper plane in the interest of the women, the nation, and civilization. He was interested in the experience of one of the speakers with appendicitis in pregnant women and wished to call attention to appendicitis as a complication of late pregnancy which was very critical. For example he was called to a woman eight or nine months in gestation who had a bad appendix and the leucocytosis was high and toxemia pronounced; it was evident that an operation must be performed. It was a fact that in a woman you would almost never find the appendix in the usual place but would find it in one of three places. First, it might be attached to the uterus in the non-pregnant woman; second, it might be behind the sigmoid, and third, up as near to the liver as it could get. Hence when a woman at or near term got appendicitis it should be attacked through a large median incision and the uterus emptied first by abdominal cesarean section. Then the uterus should be closed as cleanly as possible before dealing with the appendix, because if the appendix was operated on first the contractions of the uterus might loosen the wall of the appendix and general infection might result. The gentleman who spoke of the question of immediate closure brought up the point of what success was obtained by immediate closure. With primary repair they got 80 per cent. complete primary unions, 10 per cent. partial unions, and 10 per cent. failures. He had yet to trace infection to any such manipulation. In regard to the question of Walcher's position, he felt that they should take advantage of every position that might be of use in the management of labor. Finally, Dr. Davis said he wanted to pay his tribute to the general practitioner of medicine who dealt with these complications of labor without the hospital facilities, skilled assistants, trained nurses, and paraphernalia, that the obstetrical specialist thought were essential. They had done nobly but it was at a cost of heavy responsibility and mental and physical strain that was unjust. As to what he meant when he spoke of a specialty of diagnosis for the general practitioner, the young man who left the hospital as a general practitioner and set up in a town to practise medicine should have had obstetrical experience, and in Pennsylvania every medical graduate was required to have a definite amount of obstetrical training. Now with a proper equipment there was no more delightful field in medicine than to be a diagnostician and live one's life as the trusted adviser of a community. Such a man might never do a surgical operation, but he knew when it should be done. Such a career offered a successful, honorable, and attractive life, and one which those who knew only one specialty would envy because of the opportunity for the study of human nature. The general practitioner did not want the bad cases of labor, but when he found himself with such a case on his hands he was man enough to meet the emergency as best he could. They were looking forward, however, to the time when every practitioner should first be a diagnostician, and he would not attempt obstetrical operations, because he would be able to diagnose the presenting parts and would know when there was danger ahead and get the patient to a hospital in time to have the obstetrical specialist summoned.

Anesthesia and Eutocia.—Dr. HENRY CARL DAVIS of Chicago presented this communication, which was read by Edward B. Jones of Syracuse. He said that today obstetricians were agreed that if the method of relieving pain during labor did not increase the danger to mother or fetus it should be employed. The choice and application of the anesthetic must vary with the patient and operator just as in other surgical work. The primary consideration was not one of pain but of safety. After reviewing the history of attempts to relieve pain during labor he said that the introduction of anesthesia had revolutionized obstetrical procedure, for prior to its introduction operative procedure added greatly to the suffering of the mother and was attempted only when absolutely necessary. The general use and abuse of anesthesia certainly had not favored eutocia. This, however, did not disprove their value, but showed that they must be used by skilled physicians in suitable surroundings. There were no statistics which would indicate that the proper use of chloroform, ether, or nitrous oxide-oxygen during labor had increased the number of still births or the number of infants dying during the first week of life. The use of chloroform was open to certain dangers and ether and nitrous oxide nitrogen were to be preferred. Ether, unless contraindicated, was thought to be the anesthetic of choice for long operations during pregnancy and labor. Nitrous oxide-oxygen analgesia had proved most satisfactory for the painful second stage of labor. For the administration of nitrous oxide analgesia a few details must be observed: (1) The patient must be assured that the pain could be relieved. (2) When first administered enough gas should be administered to cause deep analgesia or even slight anesthesia. (3) One should determine the number of inhalations necessary to cause deep analgesia and then increase by one or more as the contractions became more severe. (4) One should start inhalation at the first indication of an approaching contraction. (5) A continuous analgesia might be necessary over a few contractions, but should be discontinued as soon as acute pain was controlled. Nitrous oxide-oxygen reduced the oxygen content of the maternal blood, and when given continuously over a long period of time might add to the danger of the fetus whose blood supply had been lessened by violent and frequent uterine contractions. The intermittent use of nitrous oxide-oxygen analgesia during labor was thought to be free from danger to both mother and fetus. It was given only during the first part of uterine contractions when there was practically no interchange of blood between the mother and fetus. Both chloroform and ether were eliminated slowly and therefore had a cumulative effect on both mother and fetus. The chief objection to nitrous oxide-oxygen was the cost and bulkiness of the apparatus. In the Presbyterian Hospital of Chicago its cost was $2.50 an hour and the average time it was required was three hours. The class of patients who wanted this kind of analgesia practically all went to a hospital. When nitrous oxide-oxygen was not available ether might be administered in a similar manner with beneficial results. Scopolamine and morphine might be used in the first stage and inhalation anesthesia during the second stage.

Dr. P. T. HARPER of Albany thought that in the use of anesthesia in labor distinction should be made between eutocia and dystocia. He believed that anesthesia during labor was employed too infrequently and to a less degree than was desirable. He felt that it was a moral obligation to reduce pain to the maximum extent consistent with safety. There were certain clear-cut indications for the use of anesthesia, as in patients who bore pain poorly and where there might be a reflex inhibitory action which caused contractions to disappear and caused a condition of inertia which might lead to a secondary dystocia; where the contractions were atypical and came tardily or not at all, and where the uterus failed to relax completely between contractions. Many times an asphyxia that was attributed to the use of an anesthetic was due to the condition that called for the use of the anesthetic. The argument that anesthesia prolonged labor was evidence of poor judgment on the part of the operator.

Dr. W. T. GETMAN of Buffalo said he had been using gas and oxygen for four or five years and the longer he used it the more he became convinced that it was absolutely harmless. The only objection was the expense and the bother of carrying the apparatus, and

he had found that the latter was not a great inconvenience.

Podalic Version.—Dr. Irving White Potter of Buffalo read this paper in which he stated that he had studied the question of podalic version because he thought it was a subject upon which there were many mistaken ideas. He reviewed the history of version and described the method of Braxton Hicks presented in 1860. The time to do a version depended upon the condition of the mother, the amount of dilatation of the cervix, and the condition of the fetus. All cases of labor showed slight shock, and if that could be lessened or eliminated by shortening the second stage of labor it should be done. Early version often eliminated injuries caused by prolonged labor both to mother and child. A prolonged and persistent occipital pressure might cause cystocele or rectocele in the mother and injury to the child's head, which if the child did not die within the first week might be a cause of epilepsy or idiocy. Another type of cases in which version was an advantage was in those cases in which there was a complete or partial cessation of pain with complete dilatation of the os. It had advantages in women with pendulous abdomens. In a series of 500 cases he had done a version 12 times for pendulous abdomen. Version was also an advantage in cases of mildly contracted pelvis, the so-called borderline cases, and in cases in which something had to be done to shorten labor. The conditions operating on the child for which version was an advantage were abnormal implantations of the placenta, a vicious position of the child, and cord conditions. Among rules that should be followed in doing a version were the following: The cervix must be completely dilated before attempting version. Both feet should be brought down instead of one, and the operator should work carefully. No attempt should be made to deliver the arms until the scapulæ were outside of the vulva, and then the anterior arm should be delivered first. Many children would breathe before the head was born, but the obstetrician should not hurry and should not make too much pressure on the abdomen of the mother. The mucus that the child inhaled could be cleaned off its mouth as soon as it was delivered. The aftercoming head could be delivered with forceps if necessary. It was essential always to get a good idea of the position of the child before attempting version. If the membranes were not ruptured they should be ruptured high up after having first separated them from the uterus. The lithotomy position was not always the best, but it was often the more convenient, as the Walcher position required two attendants, though it might be used by placing the patient's feet on two chairs. The writer entered a protest against spanking the new born infant to make it breathe, and advocated giving a hypodermic of pituitrin to complete the third stage.

Corpus Luteum Extract in the Vomiting of Pregnancy.—Dr. James Knight Quigley of Rochester presented this paper, in which he reported observations made on 17 cases treated with corpus luteum extract for the vomiting of pregnancy. The results corresponded fairly well with those of others. Of these 17 patients, 12 were permanently benefited, four were benefited but relapsed, and in these it was probable that insufficient extract was given. There was one complete failure. The average number of doses was seven. The preparation used was 1 c.c. ampules containing 0.2 mg. of desiccated substance of the gland. In a case presenting the pernicious form of vomiting there was no relief. In one case there was relief from profuse salivation.

Grippe of Nurslings.—Achard states that the nursling as a rule presents a pulmonary localization, the picture being either congestion, bronchitis, or bronchopneumonia. Diagnosis is made by the dyspnea, the leaden hue, cough, and local signs. Transmission in these cases is obvious, for in twenty-eight of thirty-two cases the infant derived the disease from mother or nurse. In the other four cases it was not possible to trace the origin. Of the eight patients who presented symptoms of bronchopneumonia, seven died.—*La Presse Médicale.*

Therapeutic Hints.

Dressing for Non-syphilitic Ulcers.

℞ Balsam of Peru.
Bismuth subnitrate .....āā 5v
Ichthyol
Glycerin .....āā 5xiiss
Water .....q.s.ad 5viii
M. et ft. pasta.

The raw surface of the ulcer is first cleansed with alcohol and the edges cleared. Strips of gauze impregnated with this paste, heated, are applied over the wound. This dressing can be left in place for ten days or a fortnight. One or two dressings, according to the size of the ulcer, are required, and seldom more. To promote the formation of a good epidermal covering, the patient is allowed to get up and walk about at times, so as to obtain a mechanical action of the dressing, in the nature of a massage, upon the wound.—Morlet in *Journal de Médecine de Bordeaux.*

Hemorrhoids.

℞ Tannin 5ii
Powdered camphor ..... gr.x
Powdered opium ..... gr.v
Potassium iodide ..... gr.iij
Vaseline 5i
M. et ft. unguentum molle.

—DeWolf.

Dandruff.

℞ Beta-naphthol ..... gr.xx
Oil of bergamot ..... ♏x
Vaseline 5i
M. et ft. unguentum. Sig.: Rub into the scalp at night, and in the morning shampoo with mixture of green soap.

Or ℞ Resorcinol 5i
Castor oil 5i
Ether 5ss
Cologne water 5ss
Alcohol (90 p.c.) .....q.s.ad 5iij
M. Sig.: Rub into the scalp every morning for a week.

Whooping Cough.

℞ Peroxide of hydrogen (10 vol. solution) 5iss
Glycerin 5i
Distilled water .....q.s.ad 5vi
M. Sig.: Tablespoonful in half a glassful of water from 4 to 6 times a day.—Richardson.

Flatulence in Children.

℞ Tincture of belladonna .....♏v
Aromatic spirit of ammonia... ♏xv
Bicarbonate of soda..... 5i
Peppermint water.....q.s.ad 5i
M. Sig.: Teaspoonful every six hours to a child of 2 years.

Tapeworm.

℞ Pelletierine tannate ..... gr.vii
Simple syrup 5ss
M. Sig.: On rising take a teaspoonful of fluid extract of senna; an hour later a dessertspoonful of the syrup of pelletierine and the balance in another half-hour; half an hour later one ounce of castor oil. The patient should remain in bed during the course of medication.

MEDICINE, A DETERMINING FACTOR IN WAR.*

BY ALEXANDER LAMBERT, M.D.

NEW YORK.

No one can be elected President of the American Medical Association and fail to appreciate the great honor conferred, nor fail to realize the responsibilities which may rest on him. In the recent past these responsibilities have at times lain dormant, but at other times they have actively exerted their full force, and the influence wielded by the President of this Association has had great possibilities for good or evil on the medical profession.

A year ago the problems before us were the great responsibilities of war, the conduct of that war, and the means whereby it could be pushed to a successful issue. Today, our problems still loom large, for they are those of rearrangement and reconstruction. It seems timely, therefore, to consider what the medical profession has done to fulfill its duty in the war, and what medical science has done to alleviate the dreadful horrors which, in the past, have followed in the wake of warring armies, hovering like terrible specters over the civil populations, and which sooner or later would take their death toll through epidemics of disease. We have also to consider the problems of the future and to base our actions on the lessons we have learned by the experiences through which we have so recently passed.

Response of Medical Profession to Call of Duty.—The medical profession of the United States needed no draft or conscription to answer the call to duty. About 20,000 of its members volunteered and thus expanded the small regular force of physicians in the Army and the Navy. At the outbreak of the war only 447 physicians as regulars, and about 1,600 of the Medical Reserve Corps comprised the entire commissioned personnel of the Medical Department in the regular army. In the navy, 329 surgeons, 161 naval reserve officers, and twenty-five contract surgeons comprised the medical staff. When the armistice was signed there were 35,000 medical officers in the army and 3,000 in the navy, practically 26 per cent. of the entire profession of the country.

This mobilization, added to those physicians who were taken by the draft, could not occur without great sacrifices, both by individuals and by communities, as was specially evidenced when the influenza epidemic swept over the country. But this is part of the price for war that peoples have ever paid. This mobilization of physicians was accomplished by the Surgeon-General's Office, aided by the Council of National Defense and the American Medical Association, both acting through the organized state and county societies of the American Medical Association. The wisdom and the necessity of these state organizations was never more completely demonstrated than in the last two years. Simultaneously, the justification of the necessity for The Journal of the Association, as a medium through which information could be quickly disseminated, and its great influence among physicians, was never shown more clearly. The men in the executive positions of the American Medical Association and the Council of National Defense deserve the greatest credit and deserve the acknowledgment of work well done. This tribute is but their just due, and it is with keen pleasure that I take the responsibility of speaking for the profession and publicly acknowledging it.

Work of the Local Boards.—In the work done by the medical profession in the war, one cannot pass by that accomplished in examining the young men drafted into the army. This work of the local boards was not done by picked specialists or by men previously trained for it. The physicians of the boards were at first usually the county and city physicians appointed by the local sheriff, and the figures form an interesting study. Of the 10,000,000 (9,952,735) called and registered, 6,750,000 (6,744,289) were not examined. Of the one-third who were examined—that is, of the 3,208,448—70.4 per cent. were found to be fully qualified, while 29.6 per cent. were found physically to be totally or partially disqualified. Of the 2,124,293 who were sent by the local boards to the camps and were then subjected to the careful and minute examination of experts, 91.9 per cent. were accepted and only 8.1 per cent. rejected. It is interesting to note that in the draft of 1917 the local boards rejected 29.1 per cent., and in 1918 they rejected 29.6 per cent. The more this work is studied, the more one appreciates its extent, its far-reaching influence, and the high value of the work performed.

Success of Preventive Medicine.—Few realize how crucial has been the test of preventive medicine in the war just finished. Appalling as has been the number of battle casualties, the death rate from disease has been held down as never before. The statistics available show conclusively that the great scourges and plagues of former armies have been held in check: that is, typhus

*President's address before the American Medical Association at the Seventieth Annual Session, Atlantic City, N. J., June, 1919, published by courtesy of the *Journal of the American Medical Association.*

fever, cholera, recurrent fever, typhoid, scurvy and malaria, and, not least important, smallpox. Influenza with pneumonia, occurring in an epidemic sweeping over the eastern and western hemispheres, has been the epidemic that has baffled medical science and stands out with startling distinctness as the one uncontrolled epidemic. The death toll of pneumonia has almost equaled the battle casualties of those killed and dying of wounds in the American army. In spite of the failure to control influenza and pneumonia, this is an extraordinary record of disease control, and never, in any previous war, has the knowledge of medical science and sanitation, and the application of this knowledge been able to accomplish so much. We saw typhoid start as an epidemic in Belgium, in 1914, spread with its old-time fury among the troops at that point, and then we saw it conquered by sanitation and vaccination. We have seen typhus spread with terrible fury in Serbia and in Austria, we have seen typhus and recurrent fever break out in Russia; and again we have seen the knowledge that these diseases are carried by body lice put into practical application and the epidemics controlled. Cholera has started and been controlled through sanitation and vaccination, by both Russians and Italians. Tetanus has been practically eradicated among the wounded. Smallpox, appearing among the recruits coming from civil life, has been so quickly controlled that there were, from January, 1917, to April, 1919, in the American army of over 2,000,000 men, but six deaths from this disease. To appreciate fully the meaning of this result of preventive medicine and what the American medical profession has accomplished, let us study the battle casualties and disease rates of former wars, and, by this contrast, appreciate the achievement.

Destructive Effects of Disease in Former Wars.—Of course, any accurate and minute comparison requires carefully kept statistics, and such records are available only for the wars of the nineteenth century. Surgeons and physicians have been with the armies since antiquity, but they were as part of the retinue of some king, general or noble, and were not assigned to troops. Charles the Bold of Burgundy, in the last third of the fifteenth century, was the first one that definitely assigned surgeons to the troops as well as to the officers. This seems to be the isolated instance of a single ruler, for it was not till a hundred years later that the first surgeons were supplied to the British army, in an expedition to St. Quentin. In the middle of the sixteenth century the armies of Charles V. did not possess surgeons or medical corps, for it is reported as an extraordinary occurrence that, in the siege of Metz, when Charles V., beaten by disease and famine, was forced to raise the siege of this town, his young opponent, the Duc de Guise, gathered the abandoned sick and wounded of the retreating imperial army and, contrary to the customs and traditions of the time, had them cared for by his own physician, the renowned Ambroise Paré.

However, it was not until the seventeenth century, in the time of Louis XIII. of France, that surgeons were regularly appointed to the French armies, and not till 1660, when a standing army came into existence in England, were surgeons first regularly appointed to regiments in the English army. Not till the middle of the eighteenth century, however, was there a well-organized medical service in any of the armies. Field hospitals were not thought necessary until Cardinal Richelieu installed them, in 1639, in villages behind the fighting lines.

It is not usually realized that some of the greatest wars of modern times were fought with practically no provision made for the care of the sick and wounded, that the decision of wars has at times depended more on the wastage of the armies by disease than on the valor of the soldiers or the genius of the generals. The Emperor Frederick Barbarossa, in the Middle Ages, saw one army in Italy annihilated by sunstroke. Ten years later, after he had succeeded in storming and conquering the city of Rome itself, a pestilence swept away another army, and he was forced to flee, a fugitive, to Germany. In the Thirty Years War, the Swedish army under Torstenson fought its way from the Baltic Sea to the very gates of Vienna, where the bubonic plague so decimated his forces that he was compelled to withdraw and lose the campaign so brilliantly won. In the middle of the eighteenth century the bubonic plague again so raged, this time among the Austrian and Russian armies, that these nations were forced to bring the war to an unexpected ending and to make an unfavorable peace with Turkey. In more modern times, the disorganization and discouragement produced by disease in the French forces before Sebastopol was not a small element in hurrying the government of France to conclude peace before the ultimate aims of the campaign were accomplished.

For a background of modern hygiene, let us consider the occurrence of disease in the Thirty Years War, 1618-1648, a war fought between Protestant Swedes and northern Germans, aided, toward the end, by the French, against the imperial Catholic armies of Spain, Bavaria and Austria. This war had all the bitterness of other religious wars. The armies were often an unpaid rabble of mercenaries greedy for loot, who lived on the country, but who deliberately burned and destroyed all they could not use. They methodically wasted entire districts, thus adding famine to pestilence, for wherever these armies went they took with them and spread typhus fever. The numbers engaged, relative to modern times, were small, an entire army representing no more than one or two modern divisions, the strength of either side averaging from 20,000 to 30,000, occasionally more, often less. Bodart sums up the battle casualties of the thirty greatest engagements of this war as averaging 15 per cent. for the victors and 30 per cent. for the defeated antagonist. These losses were small indeed compared to loss by disease. The sick and wounded were uncared for except by their comrades or by the camp-followers; or they were left in villages or cities to be aided by the civilians, and were universally the foci of infection from which typhus fever spread far and wide. Smallpox was ever present in the communities. Dysentery and scurvy added their toll of death in the armies; typhus fever never ceased its virulent devastation, and, after 1632, bubonic plague imposed its terrors on the armies and stricken peoples alike. Great as was the destruction of life among the soldiers, whether from battle or by disease, the loss of

life was always greater among the noncombatants, not only because of famine and pestilence, but also because of the brutal and barbaric conduct of the war. Prinzing records that the population of the city of Wurtemburg lost by war, famine and pestilence, in five years, 300,000 persons, or three quarters of its inhabitants. In the Electorate of Saxony, bubonic plague, typhus and dysentery, in two years, carried off 934,000 of the inhabitants. Three quarters of the entire population of Germany, over whose fields the war had been chiefly waged, were blotted out of existence, for the population dropped from 16,000,000 to 4,000,000, the logical consequences of barbarous warfare and no sanitation.

By the middle of the eighteenth century the armies of England and France had regularly organized medical corps. With its increased responsibilities the medical corps of England had been given an equivalent increased authority and independence, but the French medical service, from the eighteenth century even through the war of 1870, had neither independence nor authority, but was a subordinate part of the intendance, or quartermaster's department. In spite of the improved ideas of care of the sick and wounded in the armies of the eighteenth century, the mortality rate diminished but little. The hospitals were still only shelters for the very sick. Two, four, or even six patients were still crowded on a single bed. Overrun with vermin, with absolutely no ventilation, filthy beyond description, they still propagated typhus, plague and dysentery. Sir John Pringle, in discussing the causes of mortality in war, names hospitals as an important factor. And Turpin de Crisse declared that in the wars of the decade from 1731 to 1741 more men died in hospitals from lack of care than lost their lives in combat.

Typhus fever still raged as an epidemic among the armies in the Wars of the Spanish Succession, and in the Seven Years War of Frederick the Great. It was not till the nineteenth century, after the Napoleonic Wars, that the French hospitals showed any improvement. On the other hand, it was because of the experiences in the Napoleonic Wars that the English were able to improve the sanitary care of their wounded. This the historian Napier realizes, and he pays tribute to the success achieved:

> The extraordinary excellence of the medical officers may be said to have decided the day at Vittoria, for their exertions undoubtedly added a full division to the strength of Wellington's army, and without these 5,000 it is doubtful if his Lordship, with his unrivaled talent, could have carried the day.

Their efforts were directed more toward cure than prevention, although Jenner had, by the end of the eighteenth century, shown the first means of control, by preventive vaccination, of one of the decimating plagues, that of smallpox. In strange contrast to his habitual indifference to the fate of his sick and wounded, Napoleon seized on the discovery of Jenner, and by 1809 had succeeded in having his entire army vaccinated. There seems to be a general agreement that no man ever was more indifferent or cared less for the salvage of the sick and wounded of his armies than Napoleon. Duncan says that abandonment of the wounded was the rule by the French in the Napoleonic Wars. When not abandoned, they were huddled in buildings of every sort and left to die.

It is of more than passing interest that during Napoleon's war against Prussia, 1806-1807, typhoid seems to have been recognized. The French physicians at this period differentiated and accurately described its symptoms and lesions. From this time epidemics of typhoid are recognized and separated from the real typhus, which still ravaged both armies and population.

The retreat from Moscow and the Russian campaign of 1812 was probably the greatest military disaster of modern times. From recent authoritative French figures Bodart estimates that 680,000 crossed the frontier with Napoleon. Dysentery severely attacked the armies after they had crossed the Polish frontier, 80,000 men being down with it at one time. Of the 612,000 fighting strength, there returned to the frontier, according to Bodart, but 112,000 men. Lemazurier says that the great majority of the 30,000 French prisoners left at Vilna died. Faure claims that all of the French soldiers who fell into the hands of the Russians succumbed to typhus fever. It seems probable, therefore, that there were 100,000 men killed in battle, and at least 350,000 perished from starvation, cold and disease. Prinzing says that the instinct of self-preservation had kept the army together in a common line of march from Moscow to Vilna and on to Niemen. He adds:

> After crossing the river, however, at this point, the few unfortunate soldiers who had survived the awful misery of the march, hungry, with clothes in rags, with torn shoes, alive with vermin, with frozen and gangrenous limbs, scattered in all directions, some going home and others to strongholds that were in the hands of the French. Thus typhus fever, with which all parts of the army were infected, was spread in a comparatively short time over a large part of Germany.

The pursuing Russians did not escape free from the scourge, for in the three months from October to December they lost 62,000 soldiers, most of whom died from typhus. It is stated that the Russian armies in this campaign lost 200,000 killed and 150,000 wounded. The total of death by disease is not recorded.

The German campaign, a year later, was no less disastrous, and among the French and their allies there seems to have been some 60,000 killed and 196,000 wounded during 1813. Duncan thus describes the result of this campaign:

> But a few fragmentary battalions followed the eagles of Napoleon across the Rhine in November. The army lay scattered amid the villages on the route from Germany, the men dying by thousands and spreading a pestilence among the inhabitants. Reliable observers say that the retreat from Leipzig was no less ruinous than the retreat from Moscow, although there was no cold nor famine. The utter ruin of the army was the legitimate fruit of utter neglect of the sick and wounded.

Prinzing, studying the epidemic of typhus fever of 1813 and 1814, following the Russian campaign, believes that between 2,000,000 and 3,000,000 people contracted this disease, spread broadcast by the scattered armies of Napoleon, over 10 per cent of whom died.

The Spanish War, in its six years' duration, 1808-1814, cost France over 90,000 killed. The deaths by

disease are variously estimated as from 300,000 to 460,000 among the French army. We know that typhus fever was widespread and virulent. We know that yellow fever, in 1810 and 1811, raged furiously in the southern portion of Spain. It is known that in the siege of Saragossa, for example, of the 100,000 inhabitants, 54,000 died of typhus; and of the 30,000 soldiers, 18,000 died of the same disease before the city was forced to capitulate.

In striking contrast to this was the work of the English in the peninsular campaign during 1808-1811, under Sir James MacGrigor. This surgeon had been in the Walcheren expedition on the coast of Holland in 1809, when the English attempted to take Antwerp from Napoleon. This ill-fated expedition, of a strength of 42,000, lost 206 men killed and dying of wounds, but lost 8,000 through disease. Impressed by his experience on that expedition, MacGrigor made a most determined endeavor to rectify the conditions in the English army in the peninsula, and especially to fight typhus fever in the hospitals. He insisted on accurate medical statistics, so that, for the first time, the relative loss from the different causes might be known. In the two and a half years under this surgeon there were 2,699 deaths from wounds, and 14,269 from disease, which gives a death rate of killed or dying of wounds of forty-two per thousand per year, and 118 dead of disease. Typhus fever was controlled, but dysentery and typhoid caused 11,000 of the 14,000 deaths.

The Medical Corps of the American army, modeled more on English than on French lines, had not, in the Mexican War, 1846-1848, advanced far in the prevention of disease nor improved the waste of life of the Napoleonic era. The mortality from disease was 110 per thousand per year, and the battle loss was fifteen per thousand. Seven times as many men died of disease as were killed in action.

The Crimean War, 1854-1856, shows the highest loss from battle casualties among the Russians, and from disease among the French, of all wars of which we possess accurate records. The battle death rate among the British was sixty-nine per thousand per year, among the French seventy, and among the Russians 120. The disease death rate was 230 per thousand among the English, 341 among the French, and 263 among the Russians. The medical and human lessons do not lie in these mere figures, extraordinary as they are. They can be brought out only by a comparison between the mortality from disease in the English and French armies.

In the beginning of the Crimean War, the English were sent out unprepared. They had forgotten their lessons of the Peninsular War, they had discarded the knowledge so obtained, and they were absolutely unprepared for the war and went out with insufficient equipment, food, and clothing. The first winter was terribly severe. The French, on the other hand, were much better equipped and better prepared for war, were better rationed, better clothed and had good equipment. The two armies were living and fighting together, side by side in camps, under the same conditions in the same climate. They both suffered from two epidemics of Asiatic cholera, which cost the English 4,513 deaths and the French 10,044. Comparing the French and the English death rates, excluding deaths from wounds and cholera, we find that in the first eight months of the war the English lost from disease alone 9,762, and the French 9,523. But here the story changes. Intense indignation in England at the frightfully unsanitary condition and the terrible death rate of their forces produced a tremendous reaction. England rushed the military necessities of food, equipment and transport to the Crimea, and, as a consequence, from May to August, 1855, the English losses dropped to 923, but the French rose to 10,545. From September to December, 1855, the English losses were 463 and the French 8,473. In the last four months the British losses by disease were 218 and the French 17,129. Comparing the mortality of the autumn of 1854 with that of the same period in 1855, we find that there was a decrease of 80.5 per cent in the rate of the British mortality, and an increase of 62.8 per cent in the rate of the French. Comparisons of the deaths occurring from January to April, 1855, and those from January to April, 1856, reveal that there was a decrease in the British mortality of 97.05 per cent. and an increase in the French mortality of 57.43 per cent.

The details given by Garrison of these figures are even more striking. For example, during the first winter the British lost 164 men from typhus fever, and the French ninety. During the second winter the British losses from typhus were only sixteen, those of the French 10,278. The French lost 145 men from scurvy and the British 175 during the winters of 1854 and 1855; during the following winter the French lost 964, but the English had but one death from this disease. Florence Nightingale, from whose work in this war the modern system of nursing arose, describes the situation as follows:

> . . . the most complete example in history of an army, after a great disaster arising from neglect, having been brought into the highest state of health efficiency. During the first winter the mortality rate was 60 per cent., which exceeded the rate of the great plague of London. But during the last six months the mortality was not more than among the healthy guards at home, and during the last five months it was two thirds of that among the healthy troops at home. It was the most complete experiment in army hygiene, as complete as a chemical experiment in a laboratory, but which should not be repeated, even for the benefit of inquirers at home.

The cause of the French deterioration is plainly seen from a study of the correspondence of their medical inspectors and a study of the increase of sickness in the army. Surgeon-General Longmore of the English army, reviewing the medical lessons of the war, states that "the French medical officers were completely subordinated to the intendance, or direct administration, and had no authority beyond that of ordinary civil practitioners at the bedside. Even the control of hospitals, ambulances, and medical service in battle was directed by the intendance." This quartermaster's staff, having no medical training, were quite incompetent to advise on the means necessary to preserve the health of the troops, and quite incompetent to give directions on matters of hygiene and sanitation. This situation led to the development of scurvy and typhus, with

a constantly increasing virulence of these diseases, until at last their diffusion took place in such overwhelming proportion that all available resources were powerless to cope with the situation.

The short war of seven weeks' duration between Prussia and Austria, in 1866, is interesting from a medical point of view for two reasons: first, its statistics show that no improvement had been made in the Prussian army in safeguarding the health of troops or in checking the spread of disease; and second, because of this fact, within the year, the Prussian government had completed a reform of the medical service in their army, and turned it into as effective a machine to obtain the results for which it was organized as the military machine proved to be four years later in the Franco-Prussian War. This Austrian War is also noteworthy as being the first one in which the organized aid of the Red Cross societies, under the Geneva Convention of 1864, seems to have acted.

In the Franco-Prussian War of 1870, the Prussians reached the highest standard of protection against disease that any army had yet attained. The ratio of their battle casualties was fifty-five per thousand to a rate of death from disease of twenty-five. The French, however, were just the opposite. Still hampered by the quartermaster control of medical organization, in a demoralized, defeated army, they suffered battle casualties of sixty-eight per thousand and a rate of death from disease of 141. The average strength of the German army seems to have been 725,000, and their total losses were 28,500, of whom but a little over 12,000 died through disease.

Three infectious diseases had a plague-like spread in this war: these were smallpox, typhoid, and dysentery. For the first time in a large European war, typhus fever did not break out in the armies. The incidence of typhoid fever in the Prussian army was as high as ninety-three per thousand. The incidence of dysentery was forty-nine per thousand. Though smallpox occurred in only 6.1 per thousand of the fighting strength, it occurred in an army that was supposed to be vaccinated. Among the French prisoners of war, however, smallpox broke out as a plague, about 14,000 cases occurring in Germany and about 25,000 in the interned army in Belgium. The incidence was fifty-four per thousand among the prisoners in Germany, which is nine times that of the German army and shows the difference between the vaccinated and unvaccinated army. Up to this time, in Germany, the population was supposed to be vaccinated, but as is usual under noncompulsory health laws, many had neglected the precaution. Smallpox followed as an epidemic in Germany, causing the death of 170,000 persons after the war. This produced a most beneficial result in causing the passage, in 1874, of a compulsory vaccination law, the workings of which have practically eradicated the disease.

To appreciate the death rate from disease in the French army one must compare its rate of 140.8 per thousand with the death rate from disease in the German army of 24.5, or with the death rate of sixty-five per thousand in our Civil War. No accurate French statistics have been published, the situation being so bad that all have wished to forget it.

The death rate in our Civil War of killed and dying of wounds is given as thirty-three per thousand, the disease death rate as sixty-five. In the Spanish War the death rate from battle is five and the death rate from disease 30.4 per thousand. In the present war, taking the statistics up to March 28, 1919, we find the rate of death from wounds received in action is 14.191 and that of death from disease is 14.797 per thousand. This includes the army on both sides of the ocean. The statistics of the American Expeditionary Forces, with an average strength of 975,716, reveal a rate of death from wounds in action of 31.256 per thousand and a death rate from disease of 11.233. Of those who died of disease, pneumonia claimed 9.146 per thousand.

Studying comparatively the diseases of the American armies during the Civil War, Spanish-American War, and the recent war, we find that malaria was one of the chief causes of disability in both the Civil War and the Spanish-American War, though it caused but 6 per cent. of the deaths in the Civil War and but 10 per cent. in the Spanish-American War. But in the recent war malaria has caused such a small number of deaths that it is not given in detail, but is put into the aggregate term of "other diseases." Typhoid fever, with typho-malaria, so called, was the chief cause of death from disease in both the Civil War and the Spanish-American War, causing 22.4 per cent. of the deaths of the Civil War, and being the one great uncontrolled epidemic of the Spanish-American War, causing in the fighting period of the latter war 60.5 per cent. of all deaths. But in the recent war only 0.4 per cent. of the deaths are chargeable to this scourge. Pneumonia, on the other hand, causing only 13 per cent. of deaths during the four years of the Civil War and only 3 per cent. in five months of the Spanish-American War, has become the dreaded epidemic of the recent war, causing in the American army 85 per cent. of all deaths from disease. In the Civil War meningitis caused 2 per cent. of the deaths, and 2 per cent. of the deaths in the Spanish-American war, and it caused 4 per cent. of the deaths in this war. Smallpox caused 4 per cent. of the deaths in the Civil War; in the Spanish-American War one man died of this disease; in this war, one man died of smallpox in the United States and five in France. In 1918 and in the first months of 1919, there were 102 patients with smallpox admitted to the hospitals in the United States. These patients came into the various camps from civil life, for the disease developed among the recruits before they could be vaccinated and thus protected, but it has not developed at all among the vaccinated troops in the United States. Dysentery caused 28 per cent. of the deaths in the Civil War, and nearly 30 per cent. (29.3 per cent.) of the 5,600,000 cases of disease reported in that war. In the Spanish-American War it caused 5.6 per cent. of the deaths. But it caused only forty-one deaths out of 48,000 cases, or 0.08 per cent. of the deaths in the recent war. The transmission of yellow fever by mosquitos does not come into consideration in the recent war, though there were small epidemics of this disease in both the former wars, there being about 1,300 cases in the

Civil War and about 1,100 in the Spanish-American War.

There is one achievement by the Medical Department of the United States army after the Civil War which stands as a lasting monument to the industry and genius of the surgeons of that time; it is the "Medical and Surgical History of the War of the Rebellion." This was the first great medical history ever published of any war, and remains still the standard to be attained.

As a result of the scientific medical work during and after the Spanish-American War, the investigations of three American army surgeons, Jesse Lazear, James Carroll and Walter Reed, who gave to the world the solution of the problem of the transmission of yellow fever by mosquitos. With this knowledge came simultaneously the power to control this dread disease, which for centuries had been the scourge of the West Indies, and had time and again spread in devastating epidemics to this country and even to southern Europe. Lazear and Carroll laid down their lives to gain this knowledge, and paid the ultimate sacrifice in order that thousands, through their work, might be protected and live. The sanitary control of mosquitos, and thus of tropical malaria and yellow fever, and the wise administration of this knowledge, made possible the building of the Panama Canal. It was an American army surgeon, William C. Gorgas, who seized this great opportunity and transformed a pesthole of tropical diseases into a healthy and safe terrain, that the engineering genius of the United States army might be free to construct the canal. The French under De Lesseps had failed because of the epidemic and tropical diseases which were at that time uncontrollable. Disease had defied and overcome engineering skill and genius. Preventive medicine controlled and conquered.

Ten years ago the practical application of the knowledge gained from the study of the epidemic of typhoid fever of the Spanish-American War brought about the compulsory inoculation against typhoid in the United States army. It had been shown by the Vaughn and Shakespeare Board that nearly 65 per cent. of the typhoid fever of that war was transmitted by contact of man with man, and was not water borne. Hence sanitation could only reduce typhoid to a certain level and not eradicate it. The introduction of compulsory typhoid inoculation in the army has practically eradicated the disease. Following the work of the English medical corps in the Boer War, a United States army surgeon, F. F. Russell, made possible the practical application of this method in the U. S. army and proved conclusively that typhoid fever could be completely controlled. The American Army Medical Corps has, in the recent war, discovered the transmissibility of trench fever by body lice, and thus has shown the means of prevention of this new disease which, while killing no one, rendered thousands of men useless for weeks and ineffective for fighting. This discovery came to save thousands of men for the fighting lines at a time when they were urgently needed.

Modern Control of Destructive Diseases.—Medical science has today, therefore, within its grasp the power to control the diseases which, in former times, decimated warring armies and spread out from these armies among the noncombatant populations. Formerly, when war broke out, it was almost inevitably followed by some dread pestilence among the civil populations of the countries in which the war was waged. By proper sanitation and preventive inoculation, dysentery and cholera can be abolished; by vaccination armies can be protected against smallpox. Body lice disseminate typhus, recurrent fever, and trench fever, and by proper disinfestation of these vermin these diseases cease to occur. Through sanitation and preventive inoculation, typhoid fever, the scourge of the two previous wars, is absolutely controlled, and this includes also paratyphoid, which has been recognized as a separate entity only since the Spanish-American War. In the Spanish-American War, 60.5 per cent. of all deaths were caused by typhoid, and in the present war 85 per cent. were caused by pneumonia. The typhoid of the Spanish-American War was due to local causes and local epidemics. The pneumonia of this war was beyond control, and was part of a world-wide epidemic that swept over both hemispheres, and the morbidity and mortality of some of the cities of this country exceeded those of the camps. Subtracting the death rate caused by pneumonia from the total death rate by disease in the recent war, we have 2.2 per thousand for the entire army on both sides of the water, which is practically a peace-time death rate. Meningitis has caused, in this war, ten times as many deaths as typhoid fever; pneumonia has caused two hundred times as many. Mumps and scarlet fever, of the infectious diseases of the young men, remain as yet to be controlled, but they are not of great import in the armies in war. The disabling type of disease coming under the head of venereal disease has, in this war, been so controlled that the number of cases brought from civil life was greater than the number occurring in the American Expeditionary Forces in France, which was reduced to twenty-two per thousand per year, a rate only one eighth as high as the incidence among recruits coming from civil life, and only one third as high as the best that ever had been accomplished in the army before.

Influenza, measles, and pneumonia, in the respiratory group, still stand as baffling problems, and their control has not been accomplished. Measles appeared and spread until it no longer had material on which to spread, as one attack confers immunity to a second. Pneumonia, following influenza or originating as a primary disease, still eludes control. But the knowledge which we have gained in this war of the methods of its spread, of the various infectious organisms which produce it, and their various types and varying virulence, of its occurrence as a secondary complication to measles and influenza, has enormously increased. The value of the facts thus learned are incalculable, and belief is justified that the problem is better understood than ever before, and that we soon shall see the solution of these problems.

The occurrence in the camps of meningitis, another disease of the respiratory group, as far as its portal of infection is concerned, has been forty-five times as frequent in the army as its occurrence in civil life among the same age group. This has been

due to overcrowding and the diminution of air space allowed the individual soldier in badly ventilated barracks. The responsibility for these sanitary sins rests upon the General Staff and not on the Medical Corps.

Value of Lessons Learned in Determining Action in Future.—What then are the lessons that we can draw for future action? There is no question but that the salvage of human beings, the protection of troops from disease in an army, renews and saves the fighting forces. Until recently, until medical science could control disease during war time, armies had been more decimated and injured by disease than through battle casualties. Now that except for epidemic spread of respiratory diseases, the communicable and epidemic spreading diseases can practically be controlled, the medical corps of an army has become an essential part of the fighting organization. Whole nations must now go to war. No longer can they mobilize a selected portion of volunteers and send them to fight the war and defend the nation. Since all the youth of the nation must mobilize and turn to war, it becomes the duty of a general staff to save its man power and to salvage it to the greatest extent possible. The history of the Crimean War, of our Spanish-American War, and our experience in the recent war have clearly shown that only through proper representation on the general staff by those men trained in such salvage, and by experts in such knowledge of sanitation, can this duty be performed. When the General Staff of the United States Army comes to realize this fully, one cannot conceive that it will fail to give proper representation in its councils and organization to the Medical Department. The practical necessity for this was finally recognized in the A. E. F. by General Pershing and three medical officers were detailed at General Headquarters as substantive members of the General Staff. Responsibility and authority cannot be separated, and only by such organization can adequate authority equal the inevitable responsibilities.

In the mobilization of the industrial forces of the nation by the Council of National Defense, the health of the nation and the protection of both nation and its armies was regarded of such importance that it demanded direct representation of the medical profession on this board. This is also true of the navy, for its Medical Department is represented on the General Board. Oddly enough, the anachronism still exists that in the General Staff of the United States Army the Medical Department is regarded as an outsider. The safeguarding of the health and fighting vigor of an army, the salvage of its wounded, the saving of man power through protection from disease are still regarded as foreign to staff organization. The medical and sanitary formations are still regarded as noncombatants, although those serving with the troops often go forward and mingle with them in the combats, that the morale of the men may be better sustained. Duty demands it, and they have shown themselves willing, in this war, to be unarmed combatants, not noncombatants. The ratio of the medical officers killed and dying of wounds has been exceeded only by that of the infantry and artillery, which branches necessarily bear the brunt of the battles. The pro-rata death rate of the medical officers has exceeded that of aviators and of engineers.

This subject is a matter for congressional action, but the profession of this country, while the experiences of this war are still vivid in its mind, must turn to the Congress, must make an intelligent exposition of these facts, and must bring about, by legal enactment, an adequate representation of the Medical Department on the General Staff of the army.

Educational Needs of the Medical Profession.—One lesson of the war which stands out with great distinctness is the necessity for the American Medical Association to continue its unceasing struggle to raise the standards of medical education in this country. Such are the increasing demands made on the medical profession that the young men entering it to-day must realize that the broad and excellent education obtainable is none too good. It is not asking too much to require that all medical schools which are permitted to continue should soon be raised to the A Class.

There is another urgent educational need in this country that should be taken up immediately: that is, increase in the postgraduate opportunities for medical study. The opportunities that are presented in this country are practically undeveloped. It is for the profession to develop them, and every member of the Medical Corps of the army should be given an opportunity to avail himself, for a certain number of weeks each year, of the chance to study some branch of medicine or surgery at some medical center—not required to do it at his own expense, but detailed by the government to take up, for a definite number of weeks, his chosen branch of study. Physicians acquire their knowledge best by daily contact with opportunities which broaden their experiences. The opportunity to do this at short intervals, rather than at intervals of two, three or five years, would produce better results.

Need of Improved Organization.—One very important duty to be performed soon is the reorganization of the Medical Reserve Corps and the rearrangement of the Medical Reserve officers and of the medical officers of the National Guard into one National Reserve Corps. This must be done when a realization that the medical profession in the regular Medical Corps and in the Reserve and National Guard Corps are all members of one and the same profession, united in desire to serve and obtain a single objective. Those in the Regular Corps have specialized in the study of medicine in its application to military requirements. The Reserve and Guard Corps have specialized in clinical medicine, with sufficient knowledge of military requirements to permit of their early adaptation to military environment when war comes. Equal ethical responsibilities rest on all alike, since all are called together for the common purpose of caring for the sick and wounded of the army; but the amount of practical responsibility must be unevenly distributed among individuals, that proper organization may be perfected.

Authority of the individual must always equal his responsibilities. Military authority is always expressed by rank and cannot be separated from it. Hence rank, authority, and amount of responsibility must coincide. The Reserve and Guard Corps

should not be discriminated against in rank, as they have been in the past, because it invariably prevents authority from equaling responsibility, and thus cripples efficiency. One solution would be to have all Reserve Corps officers of equal rank, such as captain, and have the office held bestow the authority in proportion to the responsibilities contained therein. The administrator of each hospital unit must always have supreme local authority, but there should be an appointed group of clinical consultants in the different specialized branches of medicine, surgery, and sanitation for the proper correlation of clinical procedures, that there may be uniformly good treatment and care given equally to all sick and wounded in all hospitals. Medical and surgical specialization was developed in the army for the first time in this war, and beyond question it must remain permanently. These consultants should be utilized as medical and surgical advisers on clinical subjects to the Chief Surgeon, with direct access to him without intervening mechanism of departmental heads. It is axiomatic that these consultants must have sufficient rank and authority to equal their responsibilities, and necessarily higher rank than the commanding officers of the hospitals under their supervision. These are but suggestions, and it is unnecessary to go further into details at this time, but some solution of this problem must be found soon.

Relation of Red Cross to Army.—The relationship of the Red Cross and the army is not generally understood. The Red Cross is not a private society supported by private contributions, but is a governmental body incorporated by Congress, with a definite function, that of giving voluntary aid to the soldiers and sailors of the army and navy during war. It differs from other governmental functions in that it is not supported by congressional appropriations, but by voluntary contributions. Many of its functions and their limitation are defined in international treaties with other nations. Originally conceived to give aid to the sick and wounded in battle, and to place them and the attending medical and nursing personnel safely into a special noncombatant group, its functions have broadened and grown until they ramify, in war time, among civil and military populations alike.

When, two years ago, the war began with us, the popular idea in the army, among the majority of medical and line officers alike, of the full extent of Red Cross duties, seemed to be that the Red Cross workers were to be kept as far in the rear as possible, to hold the little hot hand of the homesick convalescent soldier, and, on off moments, make comfort bags for soldiers and sailors. The idea of the average person eager to go into Red Cross work was to make as many surgical dressings as possible and, with armfuls of these, keep as far forward in the advanced zone as possible, ready to rush on the field of battle and stem the hemorrhages of the wounded and gasping soldiers. Stern reality soon effected a compromise, and time only permits here of a short reference to some of the medical activities in their relation to the army.

The war has shown that the Red Cross has proved an excellent stop-gap for supplies, and a source of all kinds of emergency and surgical supplies and relief, even to complete and extensive hospitalization, when the situation called for them. No more satisfactory and cordial relationships could have existed between two departments than did exist in France between the Medical Department of the Red Cross and the Chief Surgeon's Office of the American Expeditionary Forces. Because of this relationship, the Red Cross was able to supply opportunities to the medical men in France which could not otherwise have been obtained. Through the broad-minded policy of Major Grayson Murphy, Red Cross Commissioner to Europe, there was formed a research committee, with American, English, and French medical men, which fostered research and secured progress in medicine even during the war. The discoveries of the origin of trench fever and its transmission through body lice was the direct result of this. The standardization of blood transfusion, the striking progress of surgery of the chest, and the continuous study of surgical shock are other examples of work accomplished by this same committee. Through the Red Cross Research Society, whose membership consisted of all members of the Medical Corps in France, this research committee furnished a forum in which was discussed and given out the knowledge of medicine and surgery of the war, gathered in the years just previous to our entry. It proved to be the intellectual center for the medical portion of the American Expeditionary Forces, and here, discussion by the Medical Corps of the British and French armies in its meetings gave to the members of the American Medical Corps the knowledge gained in the hard and cruel experiences of the three years previous to our entrance. It was by this means that the American Medical Corps started with the medical knowledge of 1917 instead of with the knowledge of 1915 or 1916. It thus trained and prepared thousands of officers by reinforcing their practical experience with knowledge of the experiences to come.

The Red Cross also published a medical journal, a digest of all war articles of the Allied countries, and disseminated these broadcast in the American Expeditionary Forces and among the medical corps of our Allies. It further disseminated knowledge by means of a library and a medical intelligence department that furnished, on request, any information regarding scientific subjects. It thus supplied medical knowledge, and prevented medical stagnation and deterioration through lack of kwowledge.

One of the unforeseen but logical sequences of the Red Cross Research Society was to establish a liaison with the medical corps of our Allies. Instead of a slow and gradual acquaintance, there arose a rapid amalgamation and a rapid fusion into a frank and trusting friendship between the medical men of France, England, and America. This proved to be one of the really valuable contributions which the Red Cross made to the war. Another contribution of great value was the making and furnishing to the army of the nitrous oxide for general anesthesia. Researches with this gas showed that, in the seriously wounded suffering from surgical shock, it did not increase this shock, as chloroform and ether did, nor did it tend to send into shock the seriously wounded. The death rate, with this general anesthetic, was 20 per cent. less among the collapsed and seriously wounded than with the other anesthetics. The Red Cross brought over to France

a plant to manufacture this gas; it manufactured it and placed it up in the front hospitals of the advanced zone. The practical proof that such an anesthetic, in huge cylinders, could be carried forward to the advanced hospitals, and used in practical abundance back of the battle lines, was a successful accomplishment. The lives saved justified the expenditures, for its advantages were so definite that its use meant the purchasing of the lives of our wounded.

Another real contribution by the Red Cross, in administrative matters in the war, was the founding of the base hospital organizations on the advice of Gen. J. R. Kean. These organizations brought together from various hospital groups of medical and surgical men and nurses who were accustomed to work together and who knew each other's ideas and ways of work, and had them fully equipped and prepared for service before war broke out. The Spanish-American War had shown how difficult it was to gather men quickly into efficient organizations with no previous acquaintance which accustomed them to work together. The base hospital units produced a homogeneous structure instead of a heterogeneous mass thrown together by haphazard, and even when members of the hospitals were taken out later and sent as leaders of other units and teams, there still remained the basic continuity, which proved of the greatest value. It is of the utmost importance for future preparedness that the Red Cross should have these base hospital groups ready to go at all times, and nothing should be allowed to stand in the way of this or of some similar plan. As is known, the Red Cross gave up these units to the army as soon as they were called to active duty.

It is a question, and one that should be fully discussed, whether or not it would be advisable for the Red Cross to retain control of the base hospitals in the rear zone of the army. This has been done in Italy, by the Italian Red Cross, with pronounced success, and the chain of hospitals continued up even into the advanced zone; but where they touched the advanced zone they left the control of the Red Cross and proceeded under the control of the army. The Red Cross can often obtain its supplies quicker than the army, and can often act independently in emergencies in which the army must proceed along more slowly acting established lines. The American Red Cross has shown conclusively in France that, with its own or with army personnel, it can furnish, equip, and efficiently run hospitals in the advanced zone, or in the rear as base hospitals. This has proved advantageous in an emergency. Would it not prove equally advantageous as an established policy?

National Control of Preventable Disease.—I desire to draw but one more logical deduction from the medical lessons of this great war, and that in reality is the climax toward which all points. That is, if this nation, through its present medical knowledge, has within its grasp the power to control communicable, and hence preventable, diseases, there must be established a nation-wide controlling organization for this purpose, a National Department of Health. Over 33 per cent. of our young men were disqualified from the draft for physical defects. There is need of wider supervision of our growing boys and girls to build up a more robust nation, and it is especially urgent in rural districts. If we are to have some form of universal military service, the very necessity of its universality demands some general supervision of the health of the youth of the nation, through protection against the transmissible diseases, and to oversee the giving of health to the people as we now give education. This war has taught that there remains economic value in the maimed and wounded, and it is our duty to develop this value to its fullest extent. The maiming and injury of our workers, in the everyday work of industry, far exceeds each year the battle casualties of this war, and there is an economic necessity and duty to be performed in the salvage and reconstruction of the industrially injured.

Malaria still prevents the use of large areas of our southern states, and saps the energy of a large portion of the population. Typhoid fever still rests as a blot on the rural hygiene of this country. The control of epidemics between states is already in the hands of the Public Health Service, and within States, if State authorities request aid. Quarantine from outside infection is also under federal control. There are many other federal activities partially supervising health and disease through the various departments of the federal government. But it all lacks the efficient power of central correlation, and there remain many public health activities that should be undertaken by central action, from some of the problems of infant mortality to the problems of the increase of degenerative diseases of late middle life. It is the duty of the American Medical Association, and of each member of each State association, to urge on Congress the establishment of a National Department of Health.

SACRAL ANESTHESIA: A PRELIMINARY REPORT.*

By PARKER SYMS, M.D., F.A.C.S.,

NEW YORK

I REGARD sacral anesthesia as such an important addition to our surgical technique that I feel that it is my duty to bring it to the attention of the profession.

By injecting about an ounce of a proper solution of novocaine into the sacral canal, one can produce complete anesthesia of the parts supplied by the sacral nerves. This makes it possible for one to perform a surgical operation in the neighborhood of the perineum, and around the anus, without pain and without the risks that attend local anesthesia on the one hand, and spinal anesthesia on the other. And of course the patient is spared all the discomfort and risks which accompany and follow the administration of a general anesthetic. Moreover, he is relieved of that peculiar dread which many people have of being rendered unconscious.

Today a large percentage of rectal cases are going to the quack because the quack has developed local anesthesia and temporizing methods, while the general surgeon has adhered to the more formal methods of operating involving the necessity of a general anesthetic.

Sacral anesthesia should do away with the quack

*Read before the Medico-Surgical Society, May 17, 1919.

in this line of work. It makes it possible for a competent operator to perform a minor operation or a major operation without pain to the patient and as far as we know with less risk than attends the ordinary methods of anesthesia.

Injecting into the sacral canal is not injecting into the spinal canal. The needle does not penetrate the dura so the fluid is entirely epidural. The nerves lying in the sacral canal are bathed with the novocaine solution, so this is a true instance of nerve blocking as distinguished from infiltration.

The use of local anesthesia by infiltration methods in the region of the anus—in the neighborhood of the hemorrhoidal plexus—is notoriously dangerous—many sudden deaths from poisoning are on record.

Hypodermic injections in an area that cannot be surgically sterilized are always liable to give rise to infection. This is one of the reasons why local anesthesia around the anus is not satisfactory.

Local anesthesia in the region of the perineum and anus has always restricted us to minor and other unsatisfactory or insufficient operative procedures.

Minor operations are often more dangerous than are larger operations for the same diseased condition—for instance—the injection of a hemorrhoid is more dangerous than the radical cure of hemorrhoids by the clamp and cautery method.

Sacral anesthesia makes it possible for us to operate in a deliberate and scientific manner on certain classes of patients who are not fit subjects for a general anesthetic, and who, therefore, would have to be condemned to endure their ills or who, at best, could have but partial relief offered to them by some incomplete method of operating.

Where it is applicable, sacral anesthesia makes it possible for us to perform a radical scientific procedure with deliberation and precision, exactly as we would proceed if the patient were under a general anesthetic.

Thus far my clinical experience has been limited, but it has been most gratifying in its results.

I have not failed to find and enter the sacral canal in every case in which I have made the attempt.

Anesthesia has been complete and satisfactory in every case, in which the technique has been properly carried out, that is to say, in every case except one. In this case an improper solution was used of insufficient strength and the anesthesia was not complete.

Dilatation of the sphincter ani is a supreme test of anesthesia. If a patient is not profoundly under ether, dilating the sphincter will make him struggle. Whenever I have attempted it with sacral anesthesia, I have been able to dilate the sphincter fully and without resistance on the part of the patient.

I have employed sacral anesthesia for hemorrhoidectomy by the clamp and cautery method—for opening prostatic abscesses—(perineal section) and for perineal prostatectomy. In these cases, it has worked with uniform satisfaction, except in the one case cited above.

Several of these patients operated upon were bad surgical risks—they were patients who in my judgment were unfit for a general anesthetic, having arteriosclerosis with advanced cardiovascular and renal lesions. By employing sacral anesthesia, these patients were taken out of the class of inoperables.

Of course, one has always the psychology of the patient to deal with. A nervous and timid patient requires a good deal of careful handling in this particular, but that will depend upon the surgeon. Some operators are not qualified to use local anesthesia—they lack the ability to properly inspire and assist their patients. Of course, this will apply to sacral anesthesia quite as much as it would to any other form of local anesthesia.

Method of Procedure.—I have followed strictly the method as described by Doctor James E. Thompson of Galveston, Texas. He has worked out the technique in a scientific manner on the cadaver as well as clinically, and has placed the procedure on a very definite footing.

The object is to introduce a hypodermic needle into the sacral canal, so one must familiarize himself with the anatomy of the sacrum, and with certain landmarks. The lower opening of the sacral canal is found at the hiatus sacralis. Of course, this is found a short distance, but a variable distance, above the upper end of the coccyx. If the coccyx is movable, it will be quite easy to locate its upper end and thus the lower end of the sacrum. If the two bones are ankylosed, it will not be so easy, but there is always an angle at the point of junction. Usually, the hiatus can be plainly palpated and recognized by the two prominent points which mark its sides.

After the needle is introduced, one can feel his way along the bone, especially if the needle is a little higher than, and a little superficial to, the hiatus, but parallel to the canal. By withdrawing the needle slowly and pressing its point against the bone, it will drop into the hiatus and can then be pushed into the canal. Of course, the needle must be introduced in a direction parallel with and posterior to the canal. In other words, it must be in the proper axis. The lower end of the canal is closed by dense fibrous membrane. One can usually feel the needle plunge through this membrane. After the membrane is penetrated the needle should not be introduced much further. Three or four cm. are sufficient. Thompson has found that the lower end of the dura is on an average 5.8 cm. from the hiatus; the shortest was 4 cm., the longest was 7 cm. The needle should be introduced detached from the syringe, so as to tell whether its point has entered the spinal canal or a blood vessel. In either case, injection should not be made. If blood flows it will show that the needle is in a vessel, probably a vein. If cerebrospinal fluid escapes, it will show that the needle has penetrated the dura. In either case, the needle should be withdrawn sufficiently and then the injection be begun. If the needle is properly within the canal, there will be no resistance to the flow of the fluid. It will be as though one were injecting into space. If the needle is not in the canal, but is in the fascia outside the canal, there will be resistance felt to the flow of the fluid. Of course the skin and superficial tissues must be anesthetized before introducing the large needle.

Thirty (30) c.c. of fluid should be employed. Three (3) No. A tablets of novocaine in this amount make the proper strength. To this should be added 10 minims of a fifty (50) per cent. solution of calcium chloride. In other words, this is about 6 grains of novocaine to an ounce of fluid.

Anesthesia should be complete in the region of the anus in twenty minutes, and it will last two or three hours. Sometimes I have injected three or four patients and then have proceeded to operate on a hernia or an appendicitis case, after finishing which the first sacral anesthesia case was taken up and then the others. By that time I have found the anesthesia was complete for the first case, and I found it had not passed off or diminished in the last case.

Thus far I have found this method to work most admirably. Instead of leaving the operating room a sick man, with hours of nausea and vomiting before him, if he has had ether; perhaps with headache and vomiting and other distressful symptoms, if he has had spinal anesthesia, the patient goes from the operating room in good spirits, with apparently no untoward symptoms. He is conscious and able to take care of himself. Most of my patients have been laughing and joking after the procedure was over and have been able to eat a meal upon returning to their beds.

361 Park Avenue.

HOW SHALL ANY COMMUNITY RID ITSELF OF TUBERCULOSIS?

By RICHARD COLE NEWTON, M.D.,

MONTCLAIR, N. J.

CONSULTING PHYSICIAN TO THE MOUNTAINSIDE HOSPITAL, MONTCLAIR; FORMERLY PRESIDENT, NEW JERSEY STATE BOARD OF HEALTH.

THE first step is unquestionably to ascertain positively how many cases of the disease are present in the community. The recent tuberculosis survey at Framingham, Mass., demonstrated, amongst other valuable truths, the futility of accepting as final the estimate of the total number of cases in a community, compiled, as is usually done, from the cases reported to the health boards by local physicians, and from the mortality returns. Whereas, there were twenty-seven cases of tuberculosis known to exist in Framingham when the demonstration started, there have been in that town under observation and treatment approximately two hundred and fifty cases since January, 1917, many of *which have become arrested and are following normal industrial pursuits.* (Italics mine.)

This work having brought to the attention of the local authorities many cases that *would not have* been discovered through the ordinary town machinery at a time when the disease *was in an early stage and when it could be cured* (Italics mine).—(D. B. Armstrong, M.D., executive officer, in Bul. Nat. Tuberculosis Ass'n, February, 1919.)

Here then is a town, the authorities of which, before trying to rid it of the curse of tuberculosis, first took the pains to ascertain definitely the nature and extent of the task before them. They knew to begin with that they had twenty-seven cases of tuberculosis to cope with, and they must have been considerably startled to find that that number was only about a tenth of the total and that while one case of tuberculosis was receiving proper care and supervision, nine were unrecognized and might be spreading the contagion in the community, while the cases themselves were passing beyond the curable stage in the development of the disease; what a valuable object lesson for every community in the United States! More than this, it is a demonstration of the only sure and scientific method of dealing with this terrible scourge. So far as the writer knows, there is no reason to suppose that the results of a demonstration in any community would conform any more nearly to the assumed number of cases in that locality than did the cases in Framingham.

If we take the City of Newark for example the alleged number of cases, as given the writer by two prominent health officials, varies between 8,000 and 20,000 and there seems to be no way to determine whether either or neither of these figures may be correct except to make an actual count of the cases present in the town. The magnitude of the task in a city of nearly half a million inhabitants is naturally very great. But if it should be done, one can not help wondering whether the actual count will show ten times as many cases to be present as the health authorities had estimated. If it should do this, taking the lower estimate as correct, it would give the city 80,000 cases to handle. Yet whether the total might reach this enormous number or not, there is no other course to pursue if permanent and satisfactory results are to be achieved.

The details of the drive in Framingham have already been published, but we will not take them up in detail here, except to quote again from Dr. Armstrong's summary of what has been accomplished in that town. He says, "Perhaps the most conspicuous result of the work has been the success which has marked the demonstration's efforts to have the community meet its own obligations along health lines. The results in this regard have demonstrated that the average American community may be depended upon to do its part in such a plan." Until this spirit can be aroused it is doubtful whether such a drive will succeed in any community. As another writer on public health puts the case, "The necessary funds to meet the expense must be assured and the community must realize that where we have been spending 15 or 25 cents per capita on health work we must spend $1 or $2 per capita if we are going to meet our obligations." Every inhabitant of Framingham got interested in the demonstration, so must every inhabitant of Newark get sufficiently interested to do his part of the work and contribute his share of the cost. In other words the fight against tuberculosis must be changed from an academic and official question into a living, earnest, domestic problem intimately affecting every household, every industry, and every individual in the community.

The first thing to do is to attack tuberculosis in a hand-to-hand combat and the only chance of success is to fight it to the death in the same manner that we fought the Germans. In this latter conflict no treasure, no life, no effort of any sort was withheld. The world must forever admire and wonder at what has been accomplished by an unprepared, non-military nation against an army alleged to be the largest and most effective ever assembled since the beginning of history. And can our people not show equal vigor, courage, and patriotism in stamping out tuberculosis, our great-

est and most ruthless foe, which has probably killed and maimed as many people in the past four years as the German nation has been able to do with its submarines, its poisonous gases, and its other diabolical agencies of destruction. Our efforts to subdue this plague have hitherto, for the most part, been unavailing because they have been too meager and because they have often been misdirected. We have, generally speaking, waited until tuberculosis has actually manifested itself, in a particular case, by the presence of physical signs in the lungs before we have begun active treatment. A fire company that waited until the house was actually enveloped in flames before starting to save the property would not accomplish a great deal. The very first indications of a conflagration must be carefully watched for and met while the fire is still controllable. How then shall we go to work to quench the fire of tuberculosis which is smoldering always in our midst and constantly attacking new victims? As said above, we must first inaugurate a demonstration to find out just how many cases there are in the town, where they live, what their surroundings may be, and all the ascertainable facts in each case.

The community must be ransacked and studied in every possible way and every case of latent or incipient tuberculosis must be brought to light and must be treated when treatment will be both effectual and economical, when the tuberculous working man need not leave his job, nor the mother her children. Even a potential case of tuberculosis is to some extent a menace to the community, and the public welfare demands that such a case shall be prevented from becoming an open and contagious case. To make this work of prevention effective our principal efforts must be directed toward the children. Not long ago there was a great movement carried out to weigh every child in America. Whether any practical use was made of the information so obtained, I do not know. But if the cases were properly tabulated and recorded a great deal of use could be made of such a mass of information. All the data so obtained should be turned over to the local health authorities for their information and guidance. As has been said above, it is not at all probable that successful drives against tuberculosis can be carried out except by intensive community effort. However, no agency must be despised and no opportunity slighted to put the work through, and whatever aid the State or general Government may be willing to render must be taken advantage of. Still the main reliance in this municipal house cleaning must be placed on the townspeople themselves. School children, churches, lodges, the police, social workers, factories, and every agency must be pressed into the work of gathering complete and accurate information. The physical status of every child in the community must be determined and recorded. Why should we wait until the child shows unmistakable symptoms of tuberculosis? As Macgown says (*Brit. Journ. Tuberculosis*, October, 1918), loss of weight in a child who should be steadily gaining should, especially if a cough is present, arouse suspicion in every case. Even if a growing child does not lose weight but merely fails to gain, the case should be investigated and every means of diagnosis should be employed to determine whether active tuberculosis is already present. MacGown's main diagnostic reliance in doubtful cases is the subcutaneous tuberculin test and this is probably our most accurate test.* Those clinicians who decry it and deny its accuracy have not mastered the technique of its application. The *x*-ray as a method of diagnosis is constantly showing itself to be more valuable, as the machines are improved and the observers grow more skillful in taking the pictures and interpreting them. The stereoradiographic examination of incipient and doubtful cases frequently gives a positive diagnosis when the physical signs are negative or inconclusive. Having then these two invaluable diagnostic methods, is it not short sighted and futile to allow, as in Framingham before the demonstration, eight or nine cases of tuberculosis to go unrecognized and untreated, in any community, for every one that is brought under observation and treatment?

Stating the proposition in this way makes it seem almost unthinkable that such a state of things should obtain at this stage of the world's history. Yet to the best of our knowledge and belief it is precisely what is going on today in nearly every city and town in this country.

The practical details of the investigation may be roughly stated as follows: First and most important will be to secure a competent director who shall be commander-in-chief of the entire antituberculosis forces. The town must be districted and a tuberculosis clinic must be established in each district. A district should contain not more than 30,000 people. A good diagnostician and administrator should be in charge of each clinic who will report directly to the director and receive orders from him. A good *x*-ray machine with an expert operator should be accessible for each clinic. Perhaps one operator and one machine could do duty for two or more clinics. A laboratory with an expert bacteriologist should be accessible in the same way for each clinic. The number of nurses and assistants attached to each clinic should be determined by the work required. Volunteer workers of all kinds should be encouraged to attach themselves to the various clinics and place themselves under the orders of the chief of clinic. One or more statisticians should be available to codify and correlate the investigations of the clinics and to oversee the statistical work. The patients should report at the clinic to which they may be attached, as often as required for observation, for instruction, and whatever treatment may be indicated in each particular case, etc. The weight and height of each patient should be recorded at least monthly, and strict watch be kept of the patient's progress. If this should be unsatisfactory every possible means should be employed to demonstrate the unfavorable factor. Classes of patients should be formed similar to those of Dr. Pratt of Boston, who has at-

*Hamman & Wolman (Tuberculin in Diagnosis and Treatment, p. 270) say: "Excellent results with tuberculin are seen in children who have been exposed to infection in their homes, whose physical signs are negative, but who are pale and weak and who give positive cutaneous or conjunctival reactions (to tuberculin tests). Such children probably have tuberculous glands concealed somewhere. At any rate they do splendidly under the treatment."

tained such marked success in treating consumptives by rest in their own homes. Enough summer camps should be established to continue the work of the open air schools, and enough Rollier institutes should be established to treat all the cases of surgical tuberculosis, and such other cases as may not be doing well, by means of the extraordinary help afforded by the sun's direct rays. The play of the children and exercises of the adults should also be carefully supervised. Food both for the anemic and incipient cases and for the advanced cases must be furnished in suitable quantities. Enough sanatorium beds should be found for the advanced and hopeless cases so that the spread of the contagion may be curtailed as far as possible. The living apartments of each suspect as well as each active case must be supervised and those tenements which are hopelessly unwholesome must be abandoned. The most important aid to the propaganda, viz., the education of the teacher and the scholar, the clergy and the laity, the medical profession and the patient must be relentlessly prosecuted. Lectures, moving pictures, concerts, and picnics must be steadily carried on and every means employed to induce the populace, high and low, learned and simple, to attend regularly. Tracts, leaflets, cards and buttons or badges should be freely used. Some little prizes should be offered to sections showing the greatest improvement in cleaning up and following out hygienic directions and bulletins should be regularly published showing the extent and the results of the work.

Such a movement can not succeed without the active cooperation of the medical profession, consequently nothing should be done to alienate the doctors. On the contrary. There should be a diagnostic clinic where any doctor could send his patient for a diagnosis; the patient to be returned to the family doctor with confidential information regarding his exact condition and the treatment recommended. The clinics should be open to the public and every step of the treatment explained. A special clinic for instruction should be regularly held for doctors and nurses. A great effort should be made to enlist the clergy and the school teachers in the work. Lectures, clinics, and demonstrations should be held for this part of the population especially, and lastly women's clubs, Red Cross workers, church and benevolent societies, the Salvation Army, and the police must be brought in. Sermons must be preached to these different classes, mass meetings must be called, and musical and social entertainments must be provided. The newspapers, the department stores, and all places where labor is employed must be interested. If any community can be induced to undertake and carry on a work of such magnitude, the result of stamping out tuberculosis will finally be achieved. If on the other hand the people of the town or city are not yet willing to pay the price, they can not expect to secure the result. No outside agency can take the place of community work and if the people will not do their part, our only recourse will be to push the propaganda of education until they realize their danger and are ready to do the necessary work and make the necessary sacrifice to overcome the ever growing menace of tuberculosis which lurks at every fireside and is proceeding in its ever stealthy march to thwart every human enterprise and render desolate every human habitation.

It was to get this question on a basis for a practical solution that the Framingham demonstration was undertaken. From this movement we now realize that no community is doing its duty to itself and its citizens that does not undertake without delay a tuberculosis demonstration and that does not prepare to follow up the demonstration with proper preventive and curative treatment of the potential and actual cases of tuberculosis. The preventive treatment is the more important and must be put into practice, as intimated above, as a police measure. Lloyd George has recently said, "Care for the health of the people is the secret of national efficiency. It is the secret of national recuperation." If the spread of tuberculosis in America shall not be arrested in a generation or two from this date, the present appalling ratio of one defective recruit for the army out of every three drafted will be indefinitely increased. In fact, we shall become a nation of invalids, passing gradually down to a state of national inefficiency and decay.

The key to the situation is *hygiene* in every form —national, public, family, personal, and individual hygiene, moral and physical righteousness. This can never be attained in a community until all the inhabitants are aroused. The school teachers must awake out of their lethargy and do their part. Every school should be an open air school. Every bedroom should have at least two windows, every purveyor of unwholesome food should be imprisoned, the enormity of in any way imperilling the public health should in every case be shown up and punished. Women who can not bear and suckle healthy children should not be allowed to marry. All this may sound utopian and unattainable. But to a man like the writer who has keenly observed for fifty years the progress of public and private health movements, it does not by any means sound impossible. In fact, if there shall be as much progress made in the advance of health regulations and the spread of the knowledge of hygiene in the next half century as in the past, very great improvement in the health and vigor of our people seems assured. We have made great progress in scientific health knowledge. The application of this knowledge is only now becoming general. The future is by no means so dark as many writers imagine, but it will take great sacrifices and persistent, unremitting efforts before we shall see this knowledge made to bear fruit in the life of the average citizen. At the present moment the fight against tuberculosis is the most pressing civic duty for all our citizens. If we can win in the conflict we can save the world; if we shall lose, the future seems dark, indeed.

Typhus Fever an Accident.—According to the decision of a tribunal in Holland, typhus fever is to be regarded as an accident in insurance medicine, the argument being that if one's occupation expose him to such accident as in the case of a physician or teacher the contraction of the disease is looked on as a hazard of the insured's calling.—*Nederlandsch Tijdschrift voor Geneeskunde.*

THE ARMY LABORATORY AND THE PREVENTION OF INFECTIOUS DISEASE.

By RALPH G. STILLMAN, M.D.,

NEW YORK.

FORMERLY MAJOR M. C., U. S. A., IN CHARGE OF LABORATORY, BASE HOSPITAL NO. 9, A. E. F.

THERE are two reasons for the selection of this topic for discussion. In the first place there has been much publicity given to the general subject of bacteriology and immunity so that every layman is able to talk to a certain extent about "bugs" and antitoxins. The newspapers give space to bacteriological announcements but unfortunately show a tendency to emphasize the spectacular aspect at the expense of scientific accuracy and conservatism so that the ideas of the general public are apt to be erroneous in many details. As a result there has arisen an impression that the immunologist is a sort of miracle worker, except among those who consider him more or less of a fakir. Even in the medical profession there are men whose ideas are very hazy concerning some of the developments of immunology and who are uncertain as to just how far published results can be relied upon.

Second, never before has the Medical Department of the Army enjoyed such power or played such an important part in military affairs as it has in this struggle. Its activity has not been limited to the surgical care of the wounded, for large numbers of men have been gathered into camps where they suffered extensively from infectious diseases and in our own army especially there was a period of nearly a year before there were wounded to be cared for.

The selection of men for the United States Army was carried out so carefully that there was a minimum of cases of chronic disease and the patients in the hospitals could be divided roughly into three groups; cases of civil surgery, so-called, including such conditions as appendicitis, hernia, etc.; the wounded; and the great group of the infectious diseases. Of course, it is understood that by infectious diseases we mean those that are caused by microorganisms.

The group of civil surgery needs but little consideration in this place. Such conditions as are due to infection are not preventable in the light of our present knowledge. Many of the others are due to mechanical faults or congenital defects and with them the laboratory has but little to do.

It is with the infectious diseases, especially those which are generally considered "medical," that the laboratory has been actively engaged. As you know, the first attempt of the bacteriologist is to discover the cause, the microorganism whose activities produce the disease. This has been done to a limited extent. The causative organisms of diphtheria, tetanus, pneumonia, and typhoid fever are well known and their various activities have been thoroughly studied. In many diseases the cause has not been satisfactorily determined although it is certain from the character and symptomatology of these affections that they are bacterial in nature. Such diseases are measles, mumps, typhus fever, and scarlet fever.

But the discovery of the cause would be a sterile accomplishment did it not lead to some effective means of therapy. The attempts to establish satisfactory methods of treatment are based upon the observation that an attack of an infectious disease generally leaves the victim more or less immune to subsequent attacks of that disease. The object of the immunologist then is to discover a way in which the man can be made immune without being subjected to the often dangerous and always disagreeable experience of passing through an attack of the disease. An immunity produced artificially may be either active or passive or a combination of the two.

An active immunity is one in which the animal produces his own immune substances in response to the introduction of some material into his body. Thus, inoculation with an emulsion of killed typhoid bacilli stimulates the production of an immunity against that organism. Smallpox vaccine is not killed, but is a virus which has been weakened in virulence by passage through the calf. Nevertheless the custom has been established of calling emulsions of killed bacteria "vaccines." An attempt is being made to popularize the term "bacterin" for these preparations but it has not yet been uniformly successful. Theoretically it would seem possible to produce an active immunity against any known bacterium by the use of a suitable vaccine. Practically this is not so. In some instances the method appears to be almost ideal but in others seems to have no effect. Typhoid fever, of course, is the disease in which the effects of the use of vaccine have been most striking. As a prophylactic procedure it has no equal and it has been repeatedly demonstrated that this disease can be very largely controlled by the use of this one measure directed by sufficient authority. At Base Hospital No. 9, A. E. F., for instance, out of 15,000 patients treated during a period of sixteen months there were but three cases of typhoid fever, and of these but one was an American soldier who had received the prophylactic treatment. Where typhoid did occur in epidemic form it was due to an overwhelming dose of infection, usually because of the presence of a "carrier" in the kitchen force. It should be emphasized that no claim should be made for absolute protection as a result of typhoid inoculation. We are not even agreed as to the intervals at which it should be repeated Still the protection afforded is of very high degree.

The value of prophylactic vaccination against pneumonia is not exactly determined. Wright found it gave some brief protection in Africa and recently Cecil and Austin and Vaughan have been able to reduce the incidence of the disease by 50 per cent. in some of our army camps by the use of a polyvalent vaccine. Vaccination for the prevention of dysentery is possible and is quite successful but was not practised as a routine because there was little need for it. The cases of bacillary dysentery were few in number and it at no time constituted a menace to the health of the troops.

Vaccines are also used in the treatment of localized infections such as furuncles, empyema, etc. The effect in this class of cases is very variable. Emulsions are made from cultures of

the pus and where the infection is a mixed one it may be very difficult to determine which organism is the one causing the trouble. When proper selection of a causative organism is made and a proper mode of administration is chosen, the results are on the whole quite favorable. There is some evidence which points to the intravenous method as the proper one for administration.

Paratyphoid fever must be considered as identical in its significance with typhoid and the prophylactic vaccine includes both organisms in one preparation.

A serious objection to active immunization, which is accomplished by the use of vaccines, is the length of time required for the development of an immunity. It is ten days after the first dose before a high degree of immunity is produced and this naturally bars this practice as a method of treatment in acute diseases. Therefore resort is had to the production of a passive immunity which is accomplished by the introduction into the patient of immune bodies produced by the active immunization of another animal. Animal immunization is obtained by inoculation with bacterial emulsions or toxins and the blood serum is used as the medium for the transmission of the immune bodies. This method confers upon the patient an immediate immunity but one which is not lasting, for the serum is broken down in the body and excreted within ten days or two weeks. So far then we can say that, as a rule, vaccines are better suited for prophylaxis and sera for treatment, though the rule is not an invariable one and is better exemplified in the more acute infections.

The two forms of immune sera which are in most general use are those for the treatment of tetanus and diphtheria. These are both antitoxins as their common name indicates. Tetanus antitoxin is used principally in a prophylactic manner though it has a definite value when the disease has once manifested itself. This is because tetanus does not produce symptoms until the infection is rather firmly established in the body. In the American Expeditionary Forces a protective dose was given to all wounded "whatever the nature or severity of the wound, as soon as possible after the infliction of the wound," and at least one subsequent dose was given at the expiration of seven days. Further, a dose was given before operation whenever the nature of the wound was such as to lead to a suspicion that it might harbor latent infection and also whenever the rectum was included in the operative field. It will be seen that while this is prophylactic treatment, it is so in a different sense than that adopted for typhoid fever, for the serum is given after the entrance of the infection though before its development. The result of the above practice was that tetanus was practically unknown in the A. E. F., just as it would be practically unknown in civil life were it possible to enforce the same regulations in as strict a manner.

Diphtheria antitoxin was given to a patient as soon as the diagnosis was made, or if it seemed that that would require too long a time, it was given to every patient who had a sore throat whose appearance was at all suspicious of diphtheria. The diagnosis can be made in the laboratory within about six hours after the receipt of a throat culture, but naturally with troops in the field it is not always possible to be so near a laboratory as to get prompt reports. As is known, clinical diagnosis of the condition is not always easy, and when in doubt it is much safer to give antitoxin. When given at the onset of the disease, antitoxin is practically a "sure cure" for the trouble. When its administration is delayed, not only must much larger doses be given but the outcome is less certain and it is often impossible to prevent the development of complications.

Diphtheria was always present in the French cities and towns so our soldiers were liable to present cases of this disease at almost any time. When a case appeared it was the practice to administer to those men who were closely associated with the patient, the "contacts," so-called, small prophylactic doses of antitoxin. When the contacts were many and conditions permitted, it was the custom to determine by means of the Schick test which ones were naturally immune and to give antitoxin only to those who were susceptible. The Schick test consists in the administration of a minute dose of toxin into the skin. Those who are immune present no reaction and number about 80 per cent. of adults. Those who are susceptible to diphtheria infection, show about the site of inoculation, within twenty-four to forty-eight hours, a small red reaction. The use of the Schick test effects a great saving of antitoxin and also avoids the necessity of sensitizing needlessly a number of men against horse serum.

It is in the prevention of diphtheria that there is used a combination of the active and passive immunization. That is, there is injected into the susceptible contacts a mixture of both toxin and antitoxin. It has been found that such a procedure results in a good degree of active immunity so that the individual may retain his protection against this infection for a relatively long period of time.

An immune serum is also used in the treatment of meningococcic meningitis. It has been administered chiefly into the subdural space, but investigations during the past two years have shown that this disease is often, if not always, a general infection at the outset and it is therefore becoming more generally a practice to give the serum intravenously as well. This treatment has brought about a distinct reduction in the mortality of the disease but there is still ample room for improvement. One reason is that meningococci can be divided into four or more groups and the serum administered should offer especial protection against the group to which the infecting organism in that case belongs. Without good laboratory service it is not possible to obtain this information within a sufficiently short time to help in the treatment.

Attempt has also been made to treat with immune sera the infections with that group of organisms known as "gas bacilli" or the bacilli of gas gangrene. The problem was a very diffi-

cult one and a very important one also, for when the infection once became well developed it was almost surely fatal. In spite of the difficulties, the laboratories of each of the armies produced sera for which were claimed good results. The claims of the French were especially remarkable. The American serum was under trial for a comparatively short time before the signing of the armistice and the results of its use are not available. The serum was to be given to all wounded in the same manner as the tetanus antitoxin and was also to be used in the treatment of the disease. The most important preventive treatment of gas gangrene still remained the surgical treatment in the advance hospitals, a subject to which we shall refer later.

The treatment of pneumonia with immune serum is practised with distinctly beneficial results but only when the infecting organism is a Type I pneumococcus. During the past winter there have been a comparatively small number of the cases which have been caused by this type of organism and for that reason the serum has not been employed as extensively as formerly. So far as our experience has gone, the anti-pneumococcus serum has no value in the prevention of the disease.

Passive immunity has also been employed in the treatment of some of the diseases whose cause is as yet unknown. This is accomplished by the use of serum derived from patients in the early stage of convalescence. The treatment has been followed principally in scarlet fever and although the results have not been remarkable they are nevertheless sufficiently good to demand serious attention.

No discussion of serum therapy can be finished without some attention being paid to anaphylaxis. It is well known that symptoms of sensitiveness may appear on the administration of serum, whether it be the first dose or a later one, and that the history of the patient is not always helpful. It is much more apt to appear when the serum is given into the vein than under other conditions. What is not quite so well known is that the appearance of the symptoms of anaphylaxis can almost always be avoided by the slow administration of a diluted serum or by a preliminary desensitization of the patient. The presence of sensitiveness can be demonstrated by the injection of a minute amount of serum into the skin, and if a reaction appears, the proper precautions may be taken. Anaphylaxis rarely results in death though the symptoms are often very alarming.

One of the most important duties of the army laboratory is to determine when a patient is in a safe condition to return to association with his organization. That is to say, the detection of carriers. For this purpose the stools of patients convalescent from typhoid and para typhoid fever and dysentery are examined culturally. Also cultures are made from the throat or pharynx of those who have had diphtheria or meningitis. These cultures must be negative before the man can return to his outfit. In those few cases in which the carrier state seems to be permanent it may be necessary to place the men so that they will furnish no menace to their associates or even to discharge them from the army. A vigorous and thorough hunt for unsuspected carriers is always a part of the investigation of an epidemic of any of the above diseases.

When specific causes are unknown one is forced to fall back upon general sanitary measures and these were usually more or less under the control of the laboratory staff. There was necessity for frequent examination of the drinking water and its careful disinfection. Then some diseases have recognized modes of transmission although their actual cause is unknown. Thus typhus, trench, and relapsing fevers are carried by lice, and infectious jaundice is spread by rats, so that it was necessary for the laboratory to supervise, to some extent, the destruction of vermin. Epidemics were carefully studied and sanitary surveys frequently made.

In the venereal diseases the services of the laboratory were limited practically to diagnosis and treatment was controlled largely on the basis of these reports.

The most remarkable therapeutic accomplishment of the war, the Carrel-Dakin treatment of wounds, depended for its greatest success upon laboratory examinations. Gas bacillus infection was largely prevented by the surgeon by thorough and complete removal of all foreign bodies and devitalized tissue at an early operation. The time of the closing of that wound then depends upon the report of the laboratory as to the variety and number of organisms which were present in the wound. Since the successful early closure of the wound not only shortens the patient's stay in the hospital but also lessens his ultimate deformity it is of the utmost importance. That the treatment is successful is shown by the published figures, that in all of the principal armies, from eighty to ninety per cent. of the wounded were able to return to combat duty. It will of course be some time before we shall be able to know the number of permanently disabled among our wounded, for the reconstruction work is still going on and will be continued for months. Still it is possible to say that the number will be exceedingly small when measured by the standards in existence before this war.

The results thus obtainable by a powerful Health Department such as the Medical Department of the army was, can be equaled in peace times but only if we are willing to give our health authorities the necessary power. In the realm of the infectious diseases it is peculiarly true that their incidence depends in large part upon the forcefulness and wisdom of powerful Health authorities. The conclusion to be drawn therefrom is obvious.

221 West Fifty-seventh Street.

Kant on Influenza.—In April, 1782, the Königsberg philosopher, expressed himself on the mode of diffusion of the influenza of his day. His view was a broad one—the infection was transmitted both by the air and by insects. These two methods of diffusion were necessary to explain the diffusibility of influenza, by land and by water, whereby alone the spread of the malady could be visualized.—*Norsk Magazin for Laegevidenskaben.*

Medical and Surgical Lessons of the War.

IMMEDIATE ACTIVE MOBILIZATION IN THE TREATMENT OF GUNSHOT WOUNDS OF JOINTS.

By Lieut.-Col. CHARLES WILLEMS,

BRUGES, BELGIUM.

SURGEON-IN-CHIEF OF THE BELGIAN MILITARY HOSPITAL OF THE FRONT AT HOOGSTADE; PROFESSOR OF CLINICAL SURGERY AT THE UNIVERSITY OF LIÉGE.

(*Concluded from page* 962)

II. Immediate Active Mobilization in Suppurative Arthritis.—My treatment of purulent arthritis consists in very extensive bilateral longitudinal incisions into the joint, followed by immediate active mobilization. In the case of non-infected lesions, absolute hermetic closure of the wound is indicated, but for infected lesions the maintenance of a free opening into the joint is necessary.

Infection may supervene in joints treated primarily by arthrotomy, excision, esquillectomy, and absolute closure, whether or not active mobilization has been practised. It is evident that the surgical preparation of a wounded joint does not always shield it from secondary infection. In other cases the wounded man is not received until several hours after the receipt of the injury, when the wound either already is, or is presumed to be, infected. In the first case, we reopen the wound; in the second, we do an arthrotomy and leave it open; in both cases we begin immediate active mobilization.

In applying mobilization in the treatment of joint suppuration my first object was to obtain effective drainage from the joint simply opened. The attempt was a most ambitious one, for every one knows that it has hitherto been impossible to drain a joint thoroughly. All measures employed to that end have shown themselves inoperative or insufficient. Incisions and counter-incisions of the greatest variety, all sorts of tubes, irrigations of every kind, have been tried in vain. It is impossible to drain a joint by the ordinary measures, which are incapable of preventing retention, and, in consequence, of arresting the progress of the infection. It is because of this insufficiency of drainage that simple arthrotomy was almost completely abandoned during the war and replaced by resection, in which a very satisfactory drainage is possible. It seemed to me, however, that to resect a joint in order to drain it was to go beyond the mark, and I sought to empty the joint cavity by expression, making it perform active movements after arthrotomy; if I should succeed in this it would restore simple arthrotomy to the place of honor, and would cause resection to be abandoned. I do not fear to assert now that this reform is actually a *fait accompli* and that we now have in immediate active mobilization a means as simple as it is efficacious of draining a joint after a simple arthrotomy.

Mode of Action of Active Movements.—In order to get a clear idea of the way in which active movements insure drainage it will be best to see what happens in the case of the knee, for the knee is the typical joint for this study. Linear longitudinal arthrotomy exposes very well the wide articular surfaces and the extensive synovial sac. If we raise the upper edge of the incision by grasping the skin with the forceps we separate the patella from the condyles and open up the entire joint cavity, and we then see what takes place during movement: Each time the patient flexes and extends the knee we see the two synovial surfaces at first come in contact, then slide one on the other, squeezing the pus toward the wound, whence it dribbles out if it is scanty, or escapes in jets if it is considerable in amount. If these movements are repeated frequently, and if they are of sufficient extent, the pus is expelled as soon as formed, no retention occurs, and an ideal drainage, without drainage tubes is realized.

The muscular contraction and the sliding of the synovial surfaces on each other result then in expression of the pus; and looking at the process more closely, we see that flexion empties especially the lateral and the sub-tricipital culs-de-sac, while extension cleans out the interosseous joint line in particular. This occurs especially at the moment that the movement of extension or flexion reaches its maximum.

From what we have seen these result: (1) The necessity of making a long incision, passing beyond the level of the sub-tricipital cul-de-sac above and the articular line below, otherwise the pus may be retained; (2) the necessity of keeping the incision constantly open throughout the whole extent, and of preventing union at the angles; (3) the necessity of reaching early the maximum excursion of the movements, since incomplete movements will allow a portion of the pus to stagnate in the joint cavity. On these three conditions, longitudinal linear arthrotomy will always suffice to insure drainage. Ordinarily it should be bilateral. It is only when the secretion is scanty that one may rest content with a unilateral incision, in which case the external one will be the more efficacious. In certain cases in which there is a popliteal wound it may be well to enlarge it in the form of a posterior arthrotomy. But it is more difficult to keep this incision open than it is the lateral ones, and it can never be utilized alone. I condemn absolutely the horseshoe incision, which has no superiority over the linear incision as regards drainage by movements, and which makes immediate active mobilization impossible.

So much for the knee. In the case of the elbow, bilateral arthrotomy is less often necessary. The joint being especially close on its inner side, it will be better drained through an external incision, and we may limit ourselves to that except in certain cases in which the secretion is very abundant, when it will be better to make a bilateral incision. Drainage will take place under excellent conditions, particularly when there is a fracture of the olecranon with loss of substance.

A suppurative arthritis treated by a wide incision and active mobilization, acts like an ordinary abscess. The suppuration is at first abundant and then subsides gradually, getting down to a few drops, and finally dries up. The arthrotomy wounds show a great tendency to become the seat early of exuberant granulations, which form voluminous masses rolling outward. The masses also press into the joint, becoming continuous with the synovial

membrane, which is red, and presents an edematous puffiness over its entire surface. This hides more or less the borders of the cartilaginous surfaces, but the latter remain healthy and preserve their normal appearance, being neither ulcerated nor detached. There is also no trace of a participation of the bone in the infection, which latter seems to be confined strictly to the synovial sac.

The knee, it is true, swells, or remains swollen, and assumes a globular aspect, but the enlargement is due especially to the tumefaction of the arthrotomy wounds. On palpation the periarticular tissues are found to be soft, not infiltrated, and one may readily make out the contour of the bone. The popliteal space especially preserves its normal consistence and suppleness, and is not painful on pressure. In no case in which the method was applied vigorously and persevered in to the end did we have a peri-articular abcess, which is the best proof that retention of the pus and extension of the infection are effectively prevented by our treatment.

The appearance and the quantity of the secretion vary, especially according to the nature of the infecting microorganism. In streptococcal arthritides suppuration is relatively slight in amount; the wound has a clean look, and is covered with a sort of glassy varnish of characteristic appearance. When other microbes are present the pus may be abundant, thick, or stringy. On the granulating surfaces, areas of dried exudate form, which serve to glue together the lips of the wound, just as the pus glues together the eyelids in cases of conjunctivitis.

At the end of a variable time, but always long—several weeks, or even months—the suppuration is reduced to an insignificant amount; pus no longer appears, except as a few drops when extreme movements of flexion or extension are made.

The nature of the microorganism seems to influence the duration of the suppurative process, the streptococcic infection lasting the longest, often for several months. It is not, other things being equal, the cases in which suppuration is most profuse at the beginning which last the longest; on the contrary, the prolonged cases are those in which the suppuration is scanty and of a glassy appearance.

As the suppuration diminishes, the arthrotomy wounds shorten, union proceeding from the two angles until finally there is only a sort of fistula remaining, which closes and then reopens from time to time to give exit to a few drops of a serous fluid. Finally, cicatrization occurs and the wound is healed.

But it is not advisable to let matters go so far as spontaneous closure of the wound. We observed in our earlier cases, in which we permitted this, that from the moment when the articulation dried up a tendency to articular stiffness was often noticeable. It is advantageous to prevent this danger by closing the wound progressively by means of secondary suture. In practice we now close one of the incisions, that one which gives exit to the lesser amount of secretion as soon as the suppuration is noticeably reduced. Later we partially suture the other wound in the part which serves least for drainage. In watching these cases we shall find indeed that after a certain period of drainage by active movements the discharge makes for itself a definite channel at one part of one of the two incisions and it is here that the terminal fistula occurs. In taking the precaution to anticipate this process by partial suture we avoid stiffening of the joint and noticeably diminish the duration of treatment. But it is advisable not to practise this secondary closure until one has acquired sufficient experience in the method and is capable of calculating exactly the opportune moment for the operation. The secondary closure has moreover the advantage of giving a better cicatrix, of allowing us to suture layer by layer, and of avoiding thereby hernias of the synovial membrane. These hernias are encountered more frequently after purulent arthritis when spontaneous closure of the arthrotomy wound has occurred than after non-infectious lesions sutured in a more careful way. These large and extensible cicatrices leave a relaxed articulation which results sometimes in a want of joint firmness which is so necessary for walking. Perhaps also this weakness of the joint plays a certain part in the causation of the effusion which sometimes occurs after complete closure of the wounds. We have observed indeed in patients who have been cured after several weeks or months and had perfect mobility and marked absence of muscular atrophy, that effusions may occur rapidly in formerly infected articulations, and sometimes in large amount, these taking place sometimes after a traumatism, as by a fall, but at other times without any appreciable cause. These effusions, like all traumatic effusions, cause a certain amount of pain and marked reduction in the extent of movement, especially in walking. We have evacuated these effusions by puncture as in ordinary hemarthrosis, the pain and functional weakness disappearing at once. The fluid removed by puncture is serous and more or less clear and is always found to be sterile. We must recognize the possibility of these little accidents following a cure in order not to overestimate their significance, and not to be tempted to perform a new arthrotomy which would be altogether useless.

Results of Perfect Drainage Obtained by These Active Movements.—In suppurative arthritis it seems indeed that the action of active mobilization is to insure a perfect drainage. It is upon this perfect drainage that most of the other advantages depend. It is due to drainage that the infection is limited to the synovial membrane alone, as we have seen above. It is also by perfect drainage that we must explain the fact that periarticular abscesses so frequent in purulent arthritis treated by classical measures are unknown in the active mobilization method. We may say that the absence or the presence of a periarticular abscess indicates whether an infected joint is being well or badly drained. Then also the perfection of the drainage has a very speedy and profound effect upon the general condition. If at the moment that the active movements are begun the temperature of the wounded man shows very marked oscillations, giving the well-known picture of septic fever—40° to 41°C. in the evening and 37° to 38°C. in the morning—the fever falls almost immediately, from the very first day, the chart showing a maximum of 38°C. in the evening and 37°C. in the morning, and

thereafter the temperature remains at a comparatively low level. If, on the other hand, the method is applied early, before the hectic phenomena have appeared, these will be wholly absent and the temperature will stay constantly at a low level, the

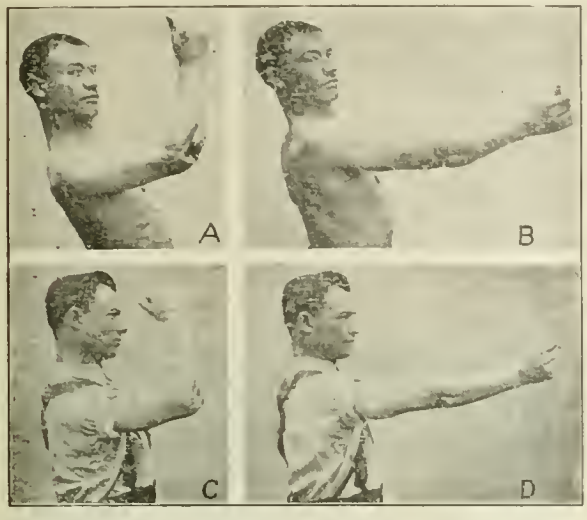

FIG. 18.—Florent de B. Extensive destruction of the right elbow, by a shell fragment, involving the olecranon, the superior ulnar epiphysis, the epicondyle, the coronoid process, and the upper third of the shaft of the radius (see Fig. 19, A). Esquillectomy was performed and the wound closed, but secondary infection occurred and on the fourth day the entire epiphysis of the ulna, which was neurotic, was removed and the radial fragments were united by screws and a plate (see Fig. 19, B). Suppuration in the joint continued for several weeks. At a later operation the plate and screws were removed. A and B, flexion and extension two and a half months after the injury; C and D, flexion and extension after eight and a half months.

curve rarely passing above 38°C. in the evening; and it is only accidentally that the temperature rises higher when for one cause or another a little retention of the secretion occurs. That is what happens when the movements are insufficient or when the incisions are too short. The fever falls

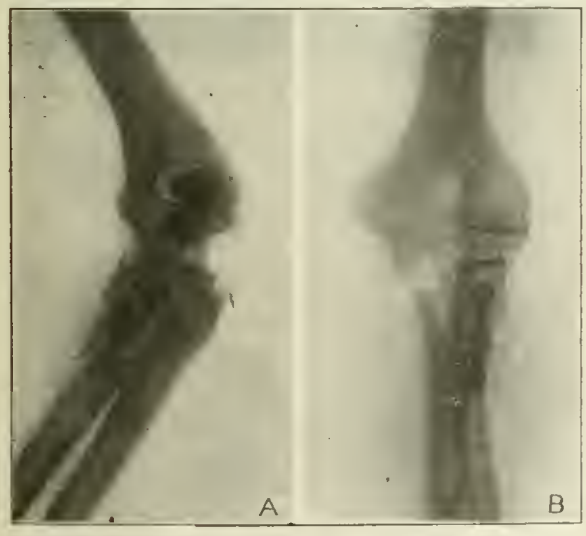

FIG. 19. *X*-ray pictures of the elbow of Florent de B. (Fig. 18).

as soon as perfect drainage of the secretion is again assured. It does not appear that the nature of the microorganism has anything to do with the height of the temperature, for a streptococcal arthritis will act during mobilization in the same way as a staphylococcal or diplococcal arthritis. As a rule the fever, while remaining very moderate, persists for several weeks. It is not rare, however, for the entire course of the disease to be almost completely apyretic. As a natural consequence of the slight febrile reaction the general condition of the patient, previously cachectic, changes almost under our eyes. The emaciation ceases and strength returns, the appetite improves, sleep returns, and all the functions become normal again, the patient losing his septic appearance. If mobilization is started at the beginning of infection, before these grave general symptoms have appeared, they re- absent and the arthritis progresses through all its stages without altering in any appreciable the general health. The patients walk about with suppurating knees or elbows protected by a simple small dressing and have the appearance of perfect health. Such are the consequences of perfect drainage obtained by active mobilization. Other advantages result from mobilization itself. The first of these is the preservation of the muscles of the limb in a normal or almost normal condition. Atrophy does not occur at all, or if it does it is very slight in degree and affects in no way the function of the limb. Another advantage is the definite preservation of movements in the joint. At the beginning my sole object in applying immediate active mobilization in cases of suppurative arthritis was to obtain drainage and I paid no attention to preserving the movements as I regarded a certain cure of the infection without ini-

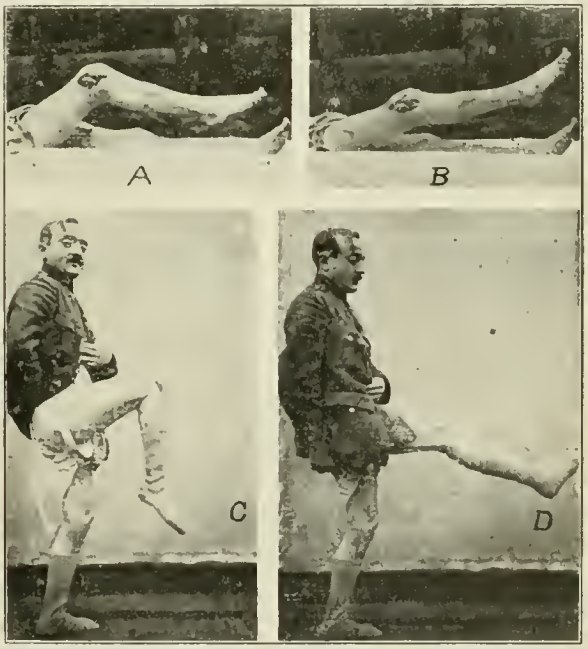

FIG. 20.—Jean B. Transverse fracture of the right patella by a rifle bullet; operation seven days later in the presence of a suppurative streptococci arthritis; cerclage (encircling by a ring of silver wire) of the patella; drainage established by a long lateral incision. Immediate active mobilization was instituted, and a final cure resulted with retained joint function. A and B, flexion and extension 17 days after the operation; C and D, flexion and extension after six months.

tial operation as in itself a remarkable progress, and thought one might be resigned to subsequent ankylosis. So it was without having sought it at all that I obtained the preservation of mobility. At the present time I can affirm that, when the

method is well applied, ankylosis may always be avoided whatever may be the microorganism causing the trouble and whatever may be the clinical gravity of the arthritis. In the great majority of cases the mobility will be absolutely normal and the limb will show no functional trace of the infection. Sometimes there may be a very little diminution in extension or flexion, but I have the impression that as we familiarize ourselves with the method we shall obtain more and more regularly complete success.

The technique of the movements is exactly the same in suppurative arthritis as in non-infected lesions; in the first as in the second the mobilization should be *immediate*, that is to say, begun immediately after the arthrotomy. This rule is perhaps even more important in suppurative arthritis than in aseptic lesions. We find considerable difficulty in getting the patient to consent to active movements when he has already been treated by another method, and it is also more difficult to obtain complete success since muscular atrophy has already begun. Mobilization ought to be *active*, done by the patient himself, by simple contraction of his muscles. Here even more than in the cases of non-infected lesions, we should absolutely never resort to passive movements which are incapable of emptying the articulation of the secretions as active movements do. As in the case of a recent and non-suppurative lesion the movements in purulent arthritis ought to be pushed to their extreme possible limits and to be repeated without interruption.

It goes without saying that mobilization should not be accompanied by any other method of drainage—tubes, gauze drains, etc. We should also absolutely do away with irrigation; a small dressing, loosely applied, should be used and renewed as it becomes soiled. An advantage of change of dressings is that the skin around the wound may be cleansed, but one should never put a finger or any instrument into the wound. Arthrotomy wounds, as we have said above, have a great tendency to close too quickly at their angles. We must oppose this premature cicatrization by separating the lips of the wound daily by forceps grasping the skin; but for this simple separation of the lips of the wound we must use only external maneuvers and never permit the introduction of the finger or of any instrument whatever into the joint cavity. It is well understood that patients affected with purulent arthritis of the knee can walk early, even before the cicatrization of the wounds, and it is curious to see them walking about with the widely open articulation which gives exit to a little pus at each step, for in walking the expression of the secretion is even more complete than in bed movements. In purulent arthritis even more than in non-infected lesions one can hardly believe at first in the possibility of early mobilization. That is a conception so far removed from the classical idea that one must actually have seen the patients move their joints before believing it possible. The truth is that active movements are perfectly possible in purulent arthritis treated by arthrotomy just as much as they are in non-infectious lesions treated by closure of the tissues and total suture. The movements are no more painful in the first case than in the second. They are equally laborious in both cases and the patient must at first make considerable efforts, but the difficulty will decrease rapidly in proportion as the movements are repeated.

In case of the knee we find that it is the raising of the heel that is at first difficult to obtain. As soon as the limb can be raised as a whole flexion and extension are executed more easily. The extent of the movements then increases until they become perfect. The time in which this complete result may be obtained varies in different cases. As I have said in speaking of the non-infected lesions, it is not merely a question of courage but also one of skill in moving the muscles by which the movements are made. The time always comes sooner or later in which active movements reach

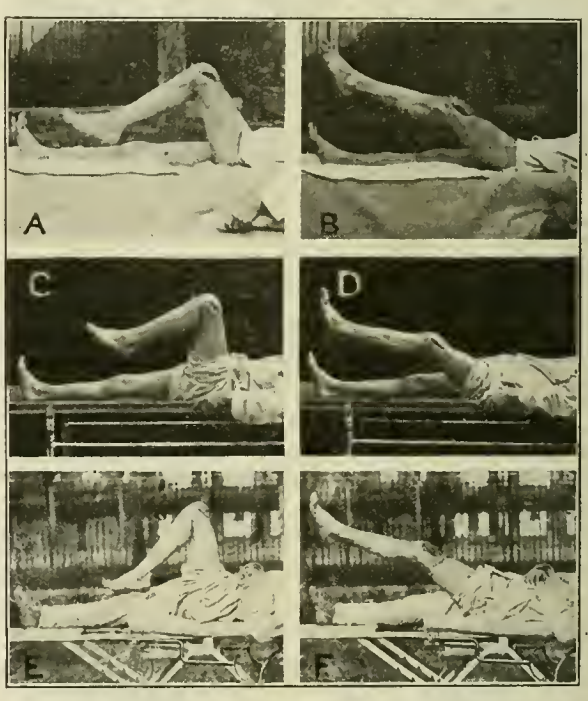

FIG. 21.—Camille R. Left knee pierced by a machine-gun bullet, causing a transverse fracture of the patella. Operation 72 hours after the injury, suppurative arthritis being already established. Catgut *cerclage* of the patella. Total closure of the operation wound, and immediately after bilateral arthrotomy for drainage. A and B, flexion and extension twenty-five days after the injury; C and D, flexion and extension after thirty-three days; E and F, flexion and extension after six weeks.

their full extent, but if this result is not obtained until late, atrophy will have had time to be produced and then the functional result will leave something to be desired although the mobility is sufficient. It must also be said that in patients already gravely infected it is often difficult to get them to make the necessary effort for vigorous muscular contractions. In consequence of this it is absolutely necessary to have some one in charge of the patient who will not leave him and whose sole duty consists in urging him constantly to make these movements. If we do not take this precaution we may be certain that the patient will not bring himself to make sufficient movements or to begin them sufficiently early, and that consequently the final result will not be satisfactory. Even more than in the case of non-infected lesions, the continuous presence of some one familiar with

the method is absolutely necessary for the success of the treatment of purulent arthritis. I would repeat what I have said before as to the enormous difference there is between really immediate mobilization and so called early mobilization. In purulent arthritis immediate mobilization alone will give perfect functional results; so-called early mobilization will give only a partial result, and late mobilization which begins when the limb is frankly atrophied, can only restore mobility but the atrophy will persist indefinitely.

We must now return again to the question of pain. I can assert that it does not exist except when pus is incompletely expressed from the joint. This pain is often produced by a very slight retention which might entirely escape the attention of the surgeon who had not been forewarned. This slight degree of retention is also ordinarily accompanied by more or less marked functional impotence and often by slight elevation of temperature. Therefore, when one of the symptoms, pain, loss of power, or fever, appears in the course of treatment by mobilization there is a strong presumption in favor of retention of pus. When the three symptoms appear simultaneously, which is more frequently the case, one may be almost absolutely certain of retention. It is very necessary to be able to recognize these signs of retention early because we must remedy it immediately, which we can do very simply by insuring the evacuation of retained pus. This may be done in one case by enlarging the wound, or in another by having the movements made more frequently and more completely. It is well to know also that the three signs of retention which I have just mentioned are sometimes preceded by pain and slight tumefaction in the popliteal space; in fact, as a rule this indicates that there is some retention of pus in the posterior intercondylean space, and we must not then wait for other symptoms before insuring better evacuation of the secretion. We ought therefore to watch carefully the arthrotomy wounds and remember that these wounds, even when the incisions were originally sufficiently long, rapidly become insufficient if one is not careful to separate their borders every day. The patients learn very rapidly in recognize themselves the cause of this increase in pain and they know that the best way of stopping it is to make more frequent and more extensive movements. This is what they do, especially on waking in the morning with a painful and stiff joint; even more than in non-infective lesions they know that a series of good movements will put an end to these symptoms.

If one believes, in spite of everything, that active movements must be painful in purulent arthritis, it will suffice to observe the action of the patient when he does not think he is being watched. It will be seen that he uses his limb without considering his movements and he moves the joint even when he is not asked to do so. This is more striking and demonstrative in purulent arthritis than in none-infected lesions.

The treatment of purulent arthritis by immediate active mobilization is only rarely interrupted by accidents other than those depending upon imperfect discharge of secretion, and it is even curious to note that no complication occurs in the course of a very prolonged treatment in which the care of the wound is reduced to the minimum and in which the long progress of the case almost invariably leads to a certain relaxation in its care. It is toward the end of the cicatrization that we must be particularly attentive, since the closure of the wound may occur too soon and the signs of retention may appear. It is necessary to recognize this terminal retention just as we must the partial retentions occurring in the course of treatment. The means to be employed are very simple and consist in puncture of the knee, and repeated puncture if necessary before the final closure of the wound. Puncture is always sufficient in these cases of terminal retention; it is never necessary to perform a new arthrotomy. It is also never necessary to resort to mechanotherapy in these cases; indeed, I believe it is actually harmful. After recovery, if there is a certain degree of muscular atrophy massage may be useful.

Infected Joint Lesions in Which Immediate Active Mobilization Is Indicated.—In my earlier papers I recognized certain contraindications to this method. I thought that it was inapplicable, (1) in cases of extensive destruction of ligaments and (2) in great loss of bony tissue. I am no longer of this opinion. The method ought to be applied in its entirety in all cases of simple suppurative arthritis in which there is no involvement of the bone and no extensive loss of the musculotendinous apparatus of the joint, but it is also applicable, partially, it is true, in suppurative arthritis accompanied by bony lesions or when the ligaments of the joint are very largely destroyed; and it is even in these complicated cases that the value of active mobilization in conjunction with conservative treatment is most striking, preserving as it does the mobility of the joint. Experience has shown me now that not only is active mobilization not contraindicated in these cases but that the functional result very far surpasses what one would have expected *a priori*. We may say that active mobilization ought to be applied in cases of suppurative arthritis with fracture to the same degree and with the same technique as in non-infected intraarticular fractures. In cases of slight so-called moderate bony lesions the technique should be applied in its entirety as if the bony parts were intact. Infection does not make active movements any more difficult, and the results which will be obtained are in every way identical with those following the treatment of similar non-infected cases. The same may be said for cases of purulent arthritis with great loss of bony substance or with extensive splintering of the epiphysis. Here again, as in similar non-infected lesions, we must treat the case by conservatism and active mobilization. In cases of comminuted fractures of the epiphysis we most combine continued extension with mobilization. Continued extension in bed reduces the fracture and fixes the fragments and furthermore permits of limited active movements. Without doubt this ultra-conservative method calls for much time and patience. It also presents many difficulties, the chief of which results from successive necroses of the splinters and from repeated sequestrotomies thereby rendered necessary. It is much easier and more expeditious to practise resection in such cases,

but the conservative treatment will give astonishing results if one only has the patience to wait for them.

At first the result from the point of view of mobility will not be very brilliant and to the surgeon who is not forewarned it may appear insufficient considering the trouble it has cost; but after cicatrization the mobility, reduced at first, increases so rapidly that I even now am daily astonished when I see old patients, the results of whose treatment had appeared slight, return with very extensive mobility of the joint. But in order to appreciate properly these results we must compare them with those of resection which leaves a shortened member and an ankylosed knee. In cases of very extensive intraarticular lesions without infection, I have stated it as my opinion that primary retention is never indicated and I can affirm that it is also not indicated in cases of extensive destruction of tissue complicated by purulent arthritis. Even secondary resection will be less and less indicated in cases of infectious intraarticular fracture in which up to a short time ago the indications for such operation appeared to be imperative. I thought myself, when I began using this method, that purulent arthritis attended by extensive destruction of the soft parts (muscles, tendons, and ligaments) of the anterior aspect of the knee could not be actively mobilized. Several facts observed since that time, however, have shown me that this is not the case. In cases of great destruction of the extensor musculotendinous apparatus, provided a few fibers are preserved, the movements are both possible and useful. It will then be necessary after cure of the arthritis to reconstruct the extensor apparatus by proper suture.

I used to think also that mobilization would not be indicated if suppuration had destroyed the crucial ligaments of the knee and this had resulted in posterior subluxation of the tibia. I had seen this accident occur in certain cases of mobilization and had then immediately stopped the active movements. Since that time, however, I have seen that in spite of this accident one may continue the active movements if continued screw extension is applied to the leg. The extension promptly reduces the subluxation and then active movements can be begun again exactly as in cases of comminuted fracture in which extension renders these movements possible by restoring the joint line. I have seen cases of purulent arthritis with subluxation healed by this method with marked resulting mobility. These, however, were extreme cases which showed well the possibilities of my method, and it is clear that in such cases the functional result will be only partial and that great and long continued efforts will be necessary in order to obtain it. It will also be necessary to begin this method early in order that the ligamentous destruction may not proceed too far; all the cases of this kind that I have seen had been mobilized too late or imperfectly. When the mobilization is done strictly according to the technique above described, and especially when it is done thoroughly, destruction of the ligaments does not occur, and a purulent arthritis with or without fracture progresses toward a perfect cure.

It is necessary then for the surgeon to grasp this idea that in purulent arthritis, either simple or complicated by small bony lesions, the functional result ought to be perfect. One should never in these cases be contented with a partial success. In cases of purulent arthritis with extensive bony lesions conservation with well conducted mobilization will give functional results infinitely superior to those of resection, but here the treatment is long and difficult. He who had the courage to undertake it will have unhoped for success which will well repay him for all his trouble.

THE UTILIZATION OF THE MUSCLES OF A STUMP TO ACTUATE ARTIFICIAL LIMBS; CINEMATIC AMPUTATIONS.*

By Professor VITTORIO PUTTI

BOLOGNA, ITALY.

PROFESSOR OF ORTHOPEDIC SURGERY IN THE UNIVERSITY OF BOLOGNA; DIRECTOR OF THE RIZZOLI INSTITUTE.

It affords me the greatest pleasure to place before the Conference the facts as to what has been called cinematic amputation. I feel this all the more because I am thoroughly convinced of the great advance which the conception of cinematization will bring about in the treatment of disabled men, and believe that all that concerns this new current of ideas, as well as the store of facts related to them, ought to be placed at the disposal of the world at large.

In briefly reviewing the fundamental theories of plastic motors, and pointing out the vast field thus thrown open to the activity of orthopedic surgeons and mechanical engineers through the practical application of these theories, I venture to express the hope that our efforts may prove welcome to all those who have hitherto had no opportunity of studying this important scientific innovation.

While in Italy the tireless work of propaganda undertaken by Dr. Giuliano Vanghetti, the original exponent of these theories, has led to their full discussion and close study and to many experiments, and while both German and Austrian scientists have been actively working to obtain the most practical application of these same theories, the medical literature of France, England, and America contains very few, if any, allusions to the subject.

In the time at my disposal I must content myself with outlining the fundamental principles upon which the theory is based, pointing out, as briefly as possible, the various ways it can be put into actual practice, and making a short statement as to the method of operation and the results; but before all else, a few words on the history of the method.

The possibility of utilizing functional resources of the stump so as to convey movement to the artificial limb was an idea that came to Dr. Vanghetti first in 1896, at the time of Italy's second expedition into Abyssinia, when soldiers who had been taken prisoners by the native forces under the Negus were cruelly tortured and maimed.

*A paper presented at the International Conference on Rehabilitation of the Disabled, under the auspices of the Red Cross Institute for Crippled and Disabled Men. New York, March 18 to 21, 1919.

From that time onward Dr. Vanghetti wrote and published many articles, wherein he developed his theory on what he had now named "cinematic amputation." Unfortunately for the speedy acceptance of this most novel and useful idea, Dr. Vanghetti, though his originality, cleverness and ability are indisputable, is not a surgeon, but a physician, and for this reason was unable to put his theory into practice. He was therefore forced to resign himself to endless delays before he succeeded in convincing surgeons of the great value and practical possibilities of his theory and obtaining their cooperation, which was indispensable to any adequate test. This was the principal reason why, prior to the war, the cases of cinematic amputations did not number more than twenty.

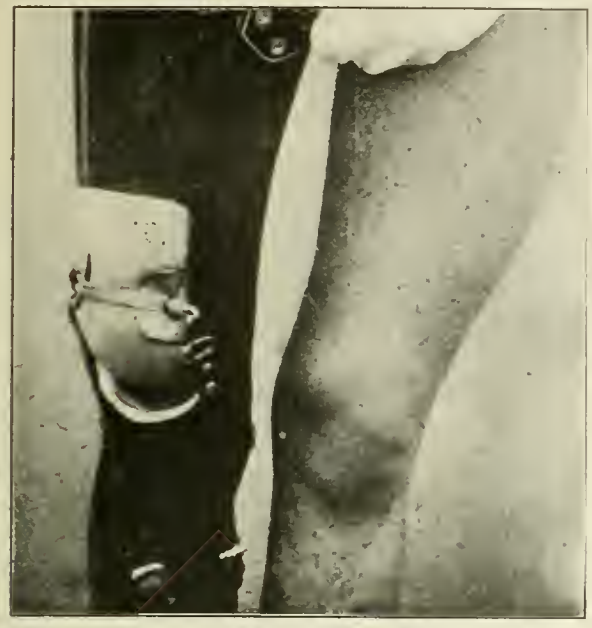

FIG. 1.—Cinematization of the thigh stump, giving good power of extension in the artificial knee-joint.

With the advent of the war, German and Austrian surgeons experimented extensively with cinematization; among them Sauerbruch became an apostle of the method. In Italy many are the surgeons who have acquired a notable experience of this science and who have brought the statistics of cinematic amputations to several hundred cases.

The Principles of Cinematization and of "Plastic Motors."—By the cinematization of a stump is meant any kind of surgical proceeding, be it bloodless or operative, which helps to make possible the direct transmission of voluntary movement from the stump to the artificial limb.

This is obtained by the formation on the stump of artificial points of attachment, so-called *plastic motors*, to which are fastened the cords or extensors destined to transmit the movement to the artificial limb. Cinematization can be effected or prepared at the time that the primary amputation is made; it can also be done on stumps that have already healed.

Plastic motors may vary as to their number, position, shape, and function.

Without entering into too detailed a description of the numerous varieties of plastic motors, I will limit myself to stating that, at the present day the most elementary, and, up to now, the most commonly used are, as regards shape, the "clava" or club, and "ansa" or loop motors, and those obtained by means of the canalizing, or tunneling, of the muscular masses.

As regards number, the motor may be single, double, or multiple; in function it can be either *unimotor* or *plurimotor*.

According to the position they occupy, motors are either *terminal*, when placed at the extremity of the stump, or *extraterminal*, should they be placed in the continuity of the stump.

Down to the present time the upper limb has been more frequently cinematized than the lower, but the number of successful cases of cinematization of the lower limbs is daily increasing.

Application of the Principles.—From what I have said, it will be evident that the application of cinematization entails essentially a radical upheaval of all preconceived notions as to the ordinary methods of amputation.

Principles observed in the performance of amputations according to prosthetic criteria have already caused a revolution in modern surgery, but they must again be subjected to modifications in order to ensure the preservation of the greatest possible amount of the original bone and of the residual motor masses and integuments, for these must be used for the preparation of the plastic motor.

In cases where it is practically impossible to perform primary cinematic plastic operations, as, for instance, at the first-aid dressing stations in the full stress of battle, the surgeon can, at any rate, always so operate as to prepare the ground for a future cinematization of the stump. Skin flaps, muscular insertions, various bone and tendinous fragments and segments of limb, which would seem utterly superfluous under ordinary circumstances

FIG. 2.—Cinematic amputation showing the power of the plastic motor in lifting a pair of iron dumb-bells.

for the preparation of ordinary stumps, must be recognized to be of the greatest value in view of the future cineplastics.

In order to prevent the possible loss of these elements and of these materials while the stump is

Fig. 3.—Cinematization of the hand, showing the plastic motors. When attached, the artificial hand is able to grasp the file and other tools used in the man's trade.

undergoing the process of healing, it is advisable to take certain special technical precautions to avoid the retraction of the softer tissues; this ought to be done, however, in such a way as not to hinder the ordinary dressing of the wound.

When the inflammation has decreased and further complications are no longer to be feared, the time has come for the actual cinematization, that is to say, for the preparation of the plastic motor or motors. A plastic motor, in order to fulfil the purpose with which it is made, must conform to the following requirements:

1. It must possess every requisite for withstanding a firm, resisting, and painless grip, and also a traction force that in not a few instances may be high.

2. It must be provided with a sufficient amount of muscle masses capable of functional movement to guarantee the accomplishment of the task that will be demanded of them.

The primary conditions for obtaining the first requisites are:

1. That the motors be covered with skin in perfect condition, well nourished, and possessing a normal degree of sensibility.

2. That, with regard to its shape and dimensions, the motor be of a size suitable for the fastening of the hooks, rings, and rods, that are destined to transmit the functional movement to the artificial limb.

The movement masses must be sought for and obtained from among those which the stump still possesses. Such masses as from their anatomical structure and physiological disposition produce broad, strong, and dissociated contractions, are the best adapted to the task. In the choice and distribution of these masses the fundamental principles of the physiology of movement must be thoroughly observed and respected.

As the tendon is the element best adapted for the transmission of muscular contractions, it should be largely employed for the formation of plastic motors. Should the tendon be missing, the muscles must be utilized either by including muscular bundles with the terminal motors, or by tunneling the muscular masses in order to obtain the extraterminal motors.

The antagonistic force, indispensable to all active movement, must be provided either by the stump itself through the formation of two motors with elements belonging to muscular groups of opposite action, or by the artificial limb by means of elastic resistance in the opposite sense to that given by the plastic motor.

In order to provide such material as may be missing *in loco*, recourse may be had to the numerous methods that modern plastic surgery places at our disposal, as, for instance, skin, muscular, aponeurotic, or osseous transplantations. Arthroplastics, with the interposition of an aponeurotic flap, may be utilized so as to render mobile those stump segments which, through stiffness and ankylosis, have become unusable. By these same means a new joint can be created in the continuity of the stump, thus giving the plastic motor the power to develop a leverage action. Often, in order to gain space and skin surface, the construction of the plastic motors requires the slight shortening of the bone or bones of the stump, but it is possible to obtain excellent plastic motors without this shortening of the skeleton, by recourse to the tunneling method of the muscular masses or of the tendons, which has been widely experimented by Sauerbruch. The building of canals through the muscles or tendons has been

Fig. 4.—Artificial hand partly attached to the plastic motors.

greatly simplified by a modification introduced by one of my assistants.

The cinematization of the thigh stump enables us to solve one of the most difficult prosthetic problems—that of gaining active power over the

knee-joint. With the ordinary artificial limbs the knee extension is obtained either by means of springs or of elastics, quite independently of the will of the patient, or else through straps put on the stretch by auxiliary movements of the trunk and shoulder. In some cases we have carried out successful experiments by cinematization of the quadriceps femoris; then the stump itself can control the voluntary extensor movement of the knee, and restrain the flexor movement.

As a result of cinematic plastics we are now able to utilize certain stumps which hitherto have always been held as incapable of functional movement, such as, for instance, carpal stumps, very short stumps, and disarticulation stumps.

The surgeon who, in the case of shoulder disarticulation, succeeds in sparing the deltoid and pectoralis major, in covering these muscles with skin, and in finding means of creating a point of attachment, may be congratulated on having preserved for the benefit of the mutilated man a precious functional capital.

With regard to the difficult problem of utilizing short forearm or short leg stumps, the solution will be enormously facilitated through the preparation of points of attachment that correspond to the insertion of the biceps and patella tendons.

At the first glance it may appear strange that mechanical attachments can be easily tolerated by the stump. Experience has proved, however, that if the plastic motor is well placed, if the skin that covers it is healthy, if the wounds are absolutely healed, neither the rings nor the rods cause the slightest harm. When the club motor is sufficiently long, and its head is large enough, the ring surrounding the neck of the club need not be tightened to such an extent as to interfere with the blood supply of the motor. Moreover, each ring is provided with a screw by means of which the disabled man can himself regulate the pressure. The same can be said of the rods introduced in the canals of the motors formed by the tunnelization of the muscular masses.

The disabled men get so accustomed to the metal rod that they leave it in place even at night. The rod must, however, be removed once every twenty-four hours, in order to clean it with alcohol and oil it with vaseline. I have observed that the skin within the canals gradually acquires the property of throwing off sebaceous substances in greater quantities than normal, thus providing for the oiling of the canal.

Functional Results.—Another point deserving consideration is the sensibility of the plastic motors. Professor Amar has made some most interesting physiological researches, showing that the superficial and deep sensibility, and the muscular sense of the stumps, which at first—that is, shortly after the amputation—are greatly altered, not only recover in time, but eventually attain a degree of sensibility superior to the normal, provided the stump is put through the proper functional training. I have observed that the same thing happens with cinematized stumps. One of my patients, on whom I operated more than a year ago, is now able to note with considerable exactitude the difference in the size and weight of the articles which he seizes with his artificial hand.

The functional results that can be obtained from a plastic motor depend upon numerous factors, but especially on the cinematic powers of the muscular masses of the stump, on the manner in which the surgeon has found it possible to utilize them, and upon the functional use the motor undergoes. To give a clear conception of the amount of work that a plastic motor can do I may state that among the cases operated upon by me, the power of the motor ranges from ten kilogram-centimeters at the lowest, to one hundred kilogram-centimeters at the highest. For a motor to be of practical use it must be contracted not less than one inch. In the case of a hip stump, I have obtained one motor that contracted to the extent of two and one-fifth inches, lifting a weight of forty-four pounds.

I have described only the principal types of plastic motors. The genius and the ability of the surgeons will find here a vast field for action. Naturally, it is not possible to treat all amputated stumps in this manner. Those that best lend themselves to it are those that include healthy muscular masses, that retain normal innervation, and that possess an ample contractility. Stumps, with rigid or ankylosed joints, covered over by skin that does not glide easily, being adherent or creased by a scar, do not supply satisfactory plastic motors. The age and moral and intellectual condition of the patient are also important. The best age is from twenty to thirty years. Disabled men of insufficient mental development, or those who are not likely to be willing to follow with patience and assiduity the necessary functional training of the stump muscles ought not to be operated upon.

FIG. 5.—Cinematic amputation of the forearm; the "flap" of the artificial hand is moved back to show the attachment to the plastic motors of the forearm.

It is to be understood that cinematization does not invariably require operations with the knife. There are stumps already formed which are endowed spontaneously with cinematic resources that, wisely employed, can be utilized for transmitting movement to the artificial limb. I will content myself with mentioning the wrist and forearm stumps, in which rotary movements are preserved, and the arm and forearm stumps that possess a terminal hood having a development and contractility sufficient to ensure a good grip.

Construction of Suitable Artificial Limbs.—Whatever type of plastic motors may be chosen, it is an essential condition for their efficient utilization to their full value that the artificial limb be

adapted in a manner suitable to their power, their number, and their shape. This question of cinematic prosthesis is so vast and still so new that it deserves a special study to itself. It is now undergoing gradual development and will bring about a substantial reform in ordinary constructive methods. The surgeon, the physiologist, and the mechanic must all collaborate intimately in this work, as only by means of the perfect fusion of these three can we obtain new methods of a really scientific character that will answer modern requirements and replace the empirical systems that have been followed up to now in the manufacture of artificial limbs.

The construction of the artificial limb is greatly simplified by the possibility of utilizing the intrinsic powers of the stump. The mechanical contrivances hitherto used for moving the fingers are most elementary; the cords, the levers, and the springs used for conveying movements to the hand by utilizing the movements of the elbow and of the shoulder can now be completely done away with, and the disabled man rendered able to open or close the fingers in any position of the limb. Even workmen's tools can be used in a practical way by the cinematized stump, and a special pincers shaped like a parrot's beak has been devised for the use of workers in metal.

Results.—As to the ultimate results of the cineplastic method, no final judgment is as yet possible, for though the idea was conceived over twenty years ago, cinematization has been applied on a larger scale only since the beginning of the war.

The very few cases of operation of this type performed prior to the war—almost exclusively by Italian surgeons—had afforded sufficient proof of the soundness of methods, but they had not provided enough material to enable us to judge with regard to their practical usefulness. Only since the beginning of the war, when the necessity of giving practical aid to the vast and tragic army of disabled men came to the fore, were our surgeons convinced of the expediency of testing the principles and methods of cinematic surgery. We are yet at the very beginning of this new scientific movement, and the surgeons of all the allied nations have not as yet contributed to it.

The German surgeons have followed Sauerbruch's example, and although they have created an admirable scientific organization, they have limited themselves to the repetition of a single type of motor. Consequently, in analyzing the results obtained by them, we can form but a partial judgment of the practical value of cinematization. The number of operations performed by Italian surgeons is probably inferior to those done in Germany, but the variety of the motors experimented upon by us is certainly greater.

It is easily understood that, for the moment, it would be impossible to make a synthesis of such a variety of facts. I believe, therefore, that it will prove of greater benefit, in discussing the results that have been obtained through cinematization, to consider the question solely and exclusively from the point of view of my own cases.

These number about one hundred examples of cinematization of the upper and lower limbs, either primary or secondary; plastic motors of various types were formed; in each case an artificial limb was applied. The functional value of the motors was studied by dynamographic and dynamometric methods, while their practical capacity was tested in the actual one of the artificial limb.

At the Instituto Rizzoli I have at my disposal a large workshop for the construction of artificial limbs, so that I have been enabled to study cinematic prosthesis as well; this, as I have already said, constitutes one of the most important sides of this complex question.

Conclusions.—The research that has been made in the Institute has brought me to the following conclusions:

I. The practical results that have been obtained through cinematization have convinced me that the hopes aroused by the principles and methods of the modern surgery of plastic motors are thoroughly well grounded. Cinematic plastics are entitled to be placed among the most brilliant of the discoveries of orthopedic surgery, deserve to be accepted with perfect confidence, and to be tested on a large scale by all those whose aim is to restore to the disabled man his functional activity.

II. The preparation of plastic motors is a well-defined surgical act that must be performed in accordance with its own special methods, which have already stood the test of experience.

III. From a physiological point of view plastic motors have been proved capable of giving both the quality and quantity of action of which the muscular masses that stimulate the said motors are capable. Yet, practically considered, plastic motors will yield the full measure of their value only if the artificial limb is perfectly adapted to their shape and their strength.

IV. As the principal aim of cinematization is to attain the vitalization of the artificial limb, it is essential that the surgeon and the artificial limb maker should work in harmony, in order to solve satisfactorily this most interesting but difficult problem.

Spread of Scarlatina by Milk.—Von Hellens traced a small epidemic of scarlatina in Helsingfors to the milk supply. The accident is not new in Finland. The milk came from an estate where had been numerous cases of the fever. No sanitary measures had been taken to protect the surroundings. A woman milker milked the cows and took care of her infected child at the same time.—*Finska Läkaresällskapets Handlingar.*

Etiology of Lymphogranulomatosis.—Naslund has investigated a case of this affection with regard to its relationship with tuberculosis. Is it due to tubercle bacilli of weak virulence, or is it only a reaction of the organism toward the organism? Most of the inoculation experiments with lymphogranulomatous matter have been negative while inoculation with a small number of bacilli or with bacilli of weak virulence has incidentally produced diffuse lesions of the disease associated however with frankly tuberculous lesions. However it is apparently unnecessary that the bacilli be of low virulence. Fully virulent bacilli were present in one case of lymphogranulomatosis, in which tuberculous lesions proper were absent. The author therefore accepts the second view that lymphogranulomatosis represents a reaction of the economy against the bacillus in general and is to all intent a form of tuberculosis.—*Upsala Läkareförenings Förhandlingar.*

THE MORTALITY FROM CANCER

THE deaths ascribed to cancer during 1917 in England and Wales number 18,145 for males, and 23,013 for females—a total of 41,158.* These figures imply the highest crude mortalities yet recorded. The rise in the male death rate is partly due to the absence of younger men as a result of the war, with a consequent relative increase in the number of men of cancer age, though even after the figures have been corrected for this excess of older men in the population the increase remains significant.

So far as the mortality among these older men (45 and upward) in 1917 can be compared with that during peace conditions, there has been some slight decline in the death rate at all ages up to 65, but a much more considerable increase at later ages. These changes may be due in part to errors in estimating the population, but they are consistent, at any rate, with the apparent tendency of the disease to become more and more one of old age. This tendency has been discussed in previous reports. While the tendency, however, has appeared in the past chiefly in the female sex, it is now less clearly manifest there than in males. The rate recorded for females has been uninfluenced by the war, and is practically the same as that of 1916.

The Registrar-General points out that when cancer deaths are classified according to the site affected, a method which has now been in operation in England and Wales for 21 years, it becomes possible to measure the rate of increase in mortality from cancer of accessible and of inaccessible sites. The comparison is important because of the light which it can shed upon the vexed question of an increase in cancer mortality. If the rise in recorded mortality were confined to cancer of inaccessible sites, it could be reasonably assumed that the increase is apparent merely, and caused by the inclusion of cases which, in earlier years, would not have been discovered. This conclusion, that the recent rise in the number of cancer deaths reported is due simply to better diagnosis was, in fact, supported by King and Newsholme in 1893, and by Willcox in 1917.

The classification of cancer in the Eightieth Annual Report as accessible or inaccessible follows practically that published in 1914 by the Bureau of the United States Census.

The Registrar-General's analysis of his figures affords at least a temporary and partial confirmation of Hoffman's view that the number of deaths from cancer is actually increasing, since it is found that the mortality from accessible cancer among males has risen more rapidly than that from inaccessible. This makes it difficult, in the opinion of the Registrar-General, to attribute so much importance to improved diagnosis as has hitherto been ascribed to it by many observers, at least in so far as males are concerned. Among females, however, the conditions are reversed.

Another test applied in the report to the hypothesis that improvement in diagnosis is an important cause of the recorded rise in mortality, is an examination of the relation of this increase to age. The increase, which becomes greater as age advances, is explained by the improved-diagnosis hypothesis on the assumption that diagnosis has been worse, and the room for improvement therefore greater, at the higher ages. If this be correct, the rise in recorded mortality as age advances should be confined mainly to the inaccessible sites, since in these alone is there any great opportunity for improvement in diagnosis. Actually, however, it is found that among males, at least, there is little difference between accessible and inaccessible cancer.

It is therefore possible that cancer mortality has been increasing, in males at any rate, and it may be that this is true also of females, though here the evidence is less convincing. The inaccuracies of most statistics, however, will render the question uncertain for years to come. Thus, there undoubtedly occur many deaths from cancer which, even today, are not recorded as such, in deference to the wishes of the family; furthermore, the statistician places more reliance upon the statistical value of death certificates than the physician, who understands only too well the inaccuracies that may be concealed beneath figures apparently so frank of face.

*Eightieth Annual Report of the Registrar-General, 1917, p. lxii. Published by His Majesty's Stationery Office, London, 1919.

ADENOMATA OF THE SUDORIPAROUS GLANDS.

IN the case of non-ulcerated adenoma of the sudoriparous glands the tumor is small, varying in size from a pea to a hazelnut, occasionally to that of an egg, but this is most exceptional. The growth may assume the form of a plaque but in the vast majority of cases it is round or oval. It projects only slightly above the surrounding skin, and in order to detect it one is sometimes obliged to use oblique lighting or palpation. The neoplasm is always single, presenting the color of healthy skin

or it may offer a slightly rosy or wine-color tint. Pigmentation may be present. A visible or dilated orifice of the gland is never found, and when the lesion is seated in a hairy region the hair falls or can be easily removed with the fingers. When these growths are palpated they are found to be hard, distinctly limited, without any peripheral area of induration. They always adhere to the skin, which may be puckered over them, but they invariably slide over the underlying structures.

Pain appears to be one of the symptoms of these morbid products, and when it has been absent at first it occurs when the growth ulcerates. It is spontaneous, and exaggerated by pressure to such an extent that it may render palpation impossible. The painful phenomenon can be explained by the nerve fibers surrounding the neoplasm and also in the changes offered in their histological structure, while in one or two instances a true plexus of nerve fibers in a state of hypertrophy has been found spreading over the tumor. The nerves may also be compressed by the fibrous shell of the growth.

When the tumor ulcerates, the ulcer is always circular in outline, and varies in size from a one cent piece to a silver dollar, and if operation be not resorted to the ulcerative process will reach much larger dimensions. The bottom of the ulcer is covered by an adherent exudate, grayish-white in hue, hiding a pulpy, fungous fundus covered by numerous large granulations. The borders of the ulcer are projecting and clean-cut and frequently possess a high degree of vascularization. The skin surrounding the tumor is raised and tense and frequently offers a slight blush. By palpation the borders and fundus of the ulcer offer in all cases a marked induration, but the neighboring lymphnodes are never enlarged. What is rather odd is that after ulceration has taken place, the pain disappears.

The evolution of sudoriparous adenoma and adenoepithelioma offers much variety. However, it may be said to be usually slow, and one case is reported where it remained stationary for some twenty years, and in two others this halt in the evolution lasted six years, but such instances are exceptional. But all that is necessary is a trauma, or irritation due to friction of the clothing, scratching, etc., in order to transform a tumor, up to the time benign, into an essentially malignant neoplasm which will then make a rapid progress. Some instances of malignancy from the start have been published and in one case the patient died from cancerous cachexia two years after first discovering his small tumor.

It is therefore clear that the prognosis of sudoriparous growths is far from being good, although it has been maintained by some that they are benign; and although it is quite true that certain of these growths have an essentially slow progress, there are others whose evolution towards ulceration is very rapid, while even metastatic phenomena may arise. But the good feature in the prognosis is the very slight tendency to recurrence after removal when this is done early.

INFLUENZA IN BATABANOS.

It has been assumed that the infection of true pandemic influenza must lurk in remote localities until the time arrives for its outbreak. A possible example of this is noted by Dr. Pons y Zamora, who relates (*Revista de medicina et cirugia de la Habana* for March 25) that in May, 1917, over one year before the outbreak of the pandemic, Batabanos was visited by a disease which was at the time regarded as dengue. The propagation was intensive rather than extensive. Many subjects in a small area were smitten within a short period of time. The condition was very benign and the absence of any semblance of an eruption made the diagnosis at least doubtful. A few cases of bronchopneumonia, which occurred during this local epidemic, were not associated with it at the time. Instead they rather suggested an enteric origin and were imputed to paratyphoid infection. Cases of meningitis during the same period were not associated with the epidemic. The author neglects to state the duration of this alleged dengue, but since there was no diffusion out of a certain region, it could not have been long. In August, 1918, a similar episode developed and was called indifferently dengue and grippe. It persisted until November, attacked 2,000 out of 6,000 inhabitants, and was extremely benign, but two deaths having occurred from bronchopneumonia. In November the picture suddenly changed to that of a most malignant disease, in which a robust man would be killed in a few hours by pulmonary edema and cardiac collapse. In short it was the same murderous pandemic which was devastating the world.

The author makes no attempt to connect the latter outbreak with the two mild endemics which preceded it. He neglects to state whether the attack of August was imported or domestic in origin. If we are not mistaken, the pandemic did not reach this locality at so early a date. There was a considerable resemblance between the two mild epidemics, both appearing in the warm months when endemic grippe is not supposed to occur. The absence of a rash appears to exclude dengue. The conviction has been expressed that true influenza must lurk in out-of-the-way places until it is roused by external factors to virulence; after which universal or more frequently partial epidemics originate. Such outbreaks are not necessarily deadly, for they may be extremely mild. We may conclude that with endemic winter grippe, dengue and three-day fever excluded, mild episodes like those in Batabanos may really be true influenza in a latent form.

CEREBRAL ACCIDENTS FOLLOWING PLEURAL INTERVENTIONS.

Amat and Bertier discuss with great thoroughness this too little known subject. Some years ago a search through the literature showed the information to be much scattered so that the present article in the *Journal de médecine et de chirurgie pratiques* for April 10 should constitute a valuable

contribution to literature. The cerebral manifestations which have followed simple puncture for diagnosis, thoracentesis, lavage, artificial pneumothorax, etc., comprise syncopal states, convulsive phenomena, hemiplegia, and other forms of paralysis, and death from various causes. The syncopal form is often fatal—indeed in the true type is probably always fatal, death occurring almost instantaneously. Naturally cases of this sort must be distinguished from transient faintness or swooning, such as might happen in any minor intervention. In the convulsive type or so-called pleural epilepsy fatalities are very common, amounting to 70 per cent. Hemiplegia persists until death and at autopsy no hemorrhage is found. It must not be understood that these accidents are isolated in the clinic for the several types may be associated or sequential. In a case reported by the authors the patient had undergone lavage of the pleural cavity for empyema a number of times without untoward developments. The sixth lavage was followed by clonic convulsions lasting only a few seconds. The patient then lay down and the lavage was safely finished. The seventh lavage was followed by the same behavior, but this time hemiplegia was added and the patient died two hours later in coma. Dyspnea had been a notable symptom.

From the monograph of Cordier (Thèse de Lyon, 1911), which deals with the nervous accidents seen in interventions for empyema—about 81 cases—it appears that these accidents while rare may be anticipated in a certain percentage of cases—about one in 25 of puncture and one in 50 of irrigation. The accidents recorded by Forlanini and others in artificial pneumothorax doubtless involve additional components, as air embolism. Numerous factors have been suspected in connection with the so-called nervous phenomena, which chiefly concern us, but are so far fetched as to be not worth a discussion. The only one with any likelihood of truth is the reflex theory, but the mechanism is obscure. The author would abandon lavage in empyema. Upon the reflex theory he would give a morphine hypodermic before puncture and other interventions. A careful technique for artificial pneumothorax as laid down by experts should exclude danger of air embolism and accidents from pressure changes. It is of course generally understood that tapping is always slowly performed in any location because of the danger of sudden lowering of internal pressure.

Intraspinous Injections of Magnesium Sulphate in Severe Chorea.

Marinesco, basing his treatment on the finds of Meltzer and Auer in the laboratory, first practised the method on four extreme sufferers from chorea in whom life was thought to have been menaced. Contrary to what was anticipated, the dangers from the method appeared to outweigh any advantages. The chief danger was from respiratory paralysis due to the action of the drug on the medulla. The alleged resources for combating this accident—preventive tracheotomy, calcium salts, physostigmine, etc.—did not appear to the author to offset the risk. The same risks had previously led some practitioners to abandon magnesia in the treatment of tetanus. But despite this Cavalieri (*Il Policlinico*, April 6) tested magnesium sulphate in a severe case of chorea by injecting it under the skin and intramuscularly in small doses, and obtained excellent results. Of a 25 per cent. aqueous solution he injected 2 c.c. two or three times daily. The patient was 13 years old, the chorea was of the rheumatic type, and mitral insufficiency had developed. The disease progressed despite the usual functional and specific medication (arsenic) and the magnesium treatment was then begun. Improvement was evident from the second day and the patient thenceforth slept well. On account of his rheumatic fever he had to keep his bed for about four weeks. He was then able to feed himself and in two more weeks was well save for his heart lesion.

Earthquake Vertigo.

The recent earthquake in Porto Rico has called attention to a form of vertigo termed seismic, which is described by Dr. del Valle Atiles in the *Boletin de la Asociacion Medica* of last March. Numerous victims complained of sensations like seasickness as a result of the trembling of the earth's surface. The latter may be very slight, hardly more than that due to the passing of a loaded dray, yet there must be something specific about it, as judged by the effects. In such cases it is possible that the major shocks in which the surface is violently agitated have sensibilized the sensorium to the minor tremblings so that a subconscious mechanism must be involved. Otherwise stated, the slight tremor awakens painful memories of the original major shocks so that a syndrome of a very complex character is set up. Weak spots in the nervous resistance seem to be lighted up so that a great variety of symptoms results. Among the latter is the sudden appearance of sugar in the urine. The author covers all of the possibilities in respect to the nature of the process, and lays special emphasis on an endocrine explanation, which he discards after a full discussion. He calls attention to the so-called "sympathetic syndrome" seen in certain individuals when an accident befalls a comrade. The author is not clear as to whether all victims of a minor crisis have been through a major experience. The neuropathic habit of some of the victims is emphasized.

Tuberculous Lymphoma and Tuberculosis.

The entire supplement of the *Upsala Läkareförenings Förhandlingar*, issued July 20, is devoted to contributions by Wallgren on this and other phases of tuberculosis. In his main contribution he deals with the relationship of scrofulous glands to future tuberculosis. He has used the material of the Upsala Chest Clinic to throw light on a subject in which contending views have long been maintained. According to the followers of Marfan child scrofula immunizes against tubercle, while Aufrecht, years before, announced the exact opposite. The author

endeavored to follow up 526 cases of surgical scrofula—cases in which operation had been performed—and obtained data in 251. He found that 95 of these were dead, while of the balance 129 could be examined by himself or other medical men. The cause of death in the 95 could be fixed so that the net number amounted to 224. It appeared that, combining the living and dead, 158 subjects had sound lungs, 62 had some form of tuberculosis in after life, of which 46 were cases of pulmonary location, while in the few scattering cases no opinion was reached. The percentage of lymphoma patients to present pulmonary tuberculosis in nearly 1,000 cases was 15 in outside material; while in the author's cases it was a little above this figure. These figures are somewhat higher than in control cases, but do not prove that lymphoma predisposes to other forms of tubercle. Apparently both Marfan and Aufrecht represented extreme viewpoints and the author's figures suggest a mean between the two.

News of the Week.

Plan to Make Brooklyn a Medical Center.—A number of the leading physicians of Brooklyn recently met at the Hamilton Club for the purpose of discussing plans for the development of a medical center in Brooklyn. It was generally agreed that Brooklyn, because of its size, situation, its wealth of clinical material, its large number of able medical men, and its numerous and well equipped hospitals was better fitted than almost any other city in the United States to furnish post graduate instruction to medical men. A second meeting has been announced at which a further discussion of the project of organizing post graduate work will be discussed. The meeting was presided over by Dr. Glentworth R. Butler.

Columbia University Confers Degrees.—Of the 1,924 students of Columbia University who received degrees at the commencement exercises on June 5, 138 had conferred upon them the degree of Doctor of Medicine. It was announced at this time that the Cartwright Prize of the School of Medicine of $500, given biennially for the best medical essay, submitted in general competition, upon any subject the writer may select, had been awarded to Dr. Abraham Leon Garbat of New York City.

Foreign Physicians and Surgeons Entertained in New York.—New York physicians gave a farewell dinner to the foreign delegates to the American Medical Association who had been sightseeing in this city for several days, at the Hotel Commodore, on the evening of June 5. Dr. Wendell C. Phillips was toastmaster. The address of welcome was made by Dr. Alexander Lambert. The other speakers were General L. Melis, Surgeon General of the Belgian Army; Sir St. Clair Thomson, and the Rev. Charles A. Eaton. The physicians left New York on June 6 to visit Baltimore, Washington, and Philadelphia before attending the sessions in Atlantic City. Dr. J. Bentley Squier was chairman of the local committee of reception.

Dr. J. Ramsey Hunt has returned from service in France and will resume practice at 20 West Fiftieth Street, New York.

Colonel R. P. Strong has been appointed acting director of the Bureau of Hygiene and Public Health of the Red Cross League.

Dr. L. D. Bristol of Augusta has resigned his position as State Health Commissioner of Maine to accept the position of Dean of the Medical College and professor of public health in the University of Tennessee, at Memphis, Tenn.

Dr. Tom A. Williams has returned from eighteen months in France as neurological adviser to the Red Cross and will resume his practice at 1621 Connecticut Avenue, Washington, D. C.

Greece Honors United States Nurses.—On June 5, King Alexander of Greece conferred the Medal of Military Merit on the Misses Sarah Addison of Baltimore; Marie Glauber of Chicago; Alma Hartz of Davenport, Iowa; Isabel Martin of San Francisco; Emily Porter of Bridgeport, Conn.; Clarissa Blakeslee of Drexel Hill, Pa.; Edith Glenn of Bristol, Pa.; and Florence Stone of Plainfield, N. J., Red Cross nurses, for their work in fighting the typhus epidemic in Macedonia.

Charitable Bequests.—The Church Home for Crippled Children at Angora, Pa., is the recipient of a bequest of $3,000, by the will of the late Emily B. Harrison of Philadelphia.

The will of the late Matilda James of Philadelphia makes a bequest of $2,500 to the Presbyterian Hospital for the endowment of a free bed.

The Jewish Seaside Home for Women, Philadelphia, receives the sum of $500, by the will of the late Rose Lowenstein.

A Plethora of German Doctors.—After having suffered from a dearth of doctors during the war due to the demands of the army, civilian Germany now finds itself over-supplied with medical men. The Leipsic Branch of the Association of Physicians of Germany summed up the situation in a recent issue of the *Berliner klinische Wochenschrift* which states that the maladjustment between the supply and demand in the field of medical employment was never so great as it is at present. The inability to find work in civilian life is most keenly felt among the younger physicians, 5,800 of whom have been graduated during the years of the war. Equally grave news come from Austria-Hungary where it is said some 700 former military doctors remain unemployed, after all openings have been filled, to whom may be added some 600 or 700 civilian doctors from German-Bohemia, the Southern Tyrol, etc., who have been driven to German-Austria because of the creation of national governments. Altogether considerably over 1,000 doctors have been made jobless through the political happenings in German-Austria. To add to their hardships the National Constitutional Convention has approved alterations in the compulsory health insurance regulations that will practically ruin the profession according to reports. Persons who can satisfy the authorities that their earned incomes do not exceed $1,000 a year are permitted to join the scheme if they so desire. The fees which doctors receive on behalf of these assured persons worked out to not more than eight cents a visit. That there will be a rush of German practitioners

to this country after the signing of the peace treaty is very certain, unless measures are taken by the authorities to refuse them a license to practise.

Government Gives Up Grand Central Palace.—The Grand Central Palace, New York, which has been used as an army base hospital since September, last will be returned to its owners on September 30, 1919, and the work of transforming it into a trade exposition building will then be begun.

Typhoid Fever Decreasing in Philadelphia.—According to figures given out by Dr. Wilmer Krusen, Health Director of Philadelphia, the number of cases of typhoid fever has been reduced from 6,587 in 1904 to 383 last year. The figure for 1918, 388, shows a reduction of 38 per cent. from the total of 1917, 625. Philadelphia now has a typhoid fever rate of 3.0 for every 100,000 of the population: in Chicago the rate is 1.4 and in Boston 2.5.

Influenza Ravages Alaska Indians.—According to cablegrams received in Seattle on June 6, one hundred and sixty natives of Bristol Bay and Unalaska, have died from influenza during the preceding ten days. Naval ships carrying surgeons and large quantities of medical supplies have been sent there, and an appropriation of $100,000 for the relief of the influenza sufferers in Alaska has been included in the general deficiency appropriation bill by the U. S. Senate.

The American Climatological and Clinical Association will hold its thirty-sixth annual meeting at the Hotel Traymore, Atlantic City, N. J., June 14-17, in conjunction with the 11th Congress of American Physicians and Surgeons. Dr. Guy Hinsdale of Hot Springs, Va., is president and Dr. Arthur K. Stone of Framingham Center, Mass., secretary.

Medical Society Elections.—The Essex South Medical Society (Mass.), at its annual meeting, held at Nahant, May 15, 1919, elected the following officers for the ensuing year: *President*, Dr. W. T. Hopkins, Lynn; *Vice-President*, Dr. R. E. Foss, Peabody; *Secretary*, Dr. G. E. Tucker, Salem; *Treasurer*, Dr. G. Z. Goodell, Salem.

The Late Dr. Lyle.—At the June meeting of the Medical Board of the City Hospital the following resolution relative to the death of the late Dr. Alexander Lyle was passed:

Whereas: In the death of Dr. Alexander Lyle, a member of the Surgical Visiting Staff of the City Hospital, we have lost a fellow member and valued friend, whose cheerful kindliness and good fellowship endeared him to the Board, a man whose skill in his chosen specialty had made him a valuable addition to the Surgical Staff of the City Hospital;

Be it resolved: That we make this resolution a part of the minutes of the June meeting and the Secretary be advised to express the sympathy of the Board to his family.

Obituary Notes.—Dr. Adolph Brand, a graduate of the College of Physicians and Surgeons, New York, in 1904, died at his home in New York City, on June 2, aged 38 years. He was dermatologist to the Hospital for Deformities and Joint Diseases, chief dermatologist to St. Bartholomew's Clinic, and assistant dermatologist to Bellevue Clinic. He was a member of the American Urological Society, the New York Academy of Medicine, and the Medical Society of the County of New York.

Dr. Samuel Thomas Tapscott, Sr., a graduate of Memphis Hospital Medical College, in 1858, died at his home in Searcy, Ark., on May 14, aged 88 years.

Dr. H. C. Rafferty, a graduate of Willamette University Medical Department, in 1869, died following a paralytic stroke at his home in Portland, Ore., on May 10, aged 80 years. He was one of the first mayors of East Portland, and held a number of other city offices.

Dr. David G. Murrell of Paducah, Ky., a graduate of the Kentucky College of Medicine, Louisville, in 1878, formerly chief surgeon of the Illinois Central Hospital, died in New Orleans, where he had been residing for some time past, on May 17, aged 70 years.

Dr. Edwin Everett Smith, formerly of Norwalk, Conn., a graduate of the Long Island College Hospital, in 1871, died at his home in Cold Spring, N. Y., on May 24, aged 74 years.

Dr. Jedediah Howe Adams died at Philadelphia, on May 25, at the age of 52 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1889. He was a member of the Philadlphia County Medical Society, the Medical Society of Pennsylvania, and the American Medical Association.

Dr. J. Allen Harrison died at Philadelphia, on May 25, at the age of 47 years. He was graduated from Hahnemann Medical College and Hospital of Pennsylvania in the class of 1892. He was a member of the Oxford Medical Society, the Germantown Medical Society, and the Tioga Medical Society.

Dr. Charles Biddle Bush died at Philadelphia, on May 27, at the age of 58 years. He was graduated from Jefferson Medical College in the class of 1885. He was a member of the Philadelphia County Medical Society and of the Medical Society of the State of Pennsylvania, and of the American Medical Association.

Dr. Oliver Grimshaw died at Swedesboro, N. J., on May 27, at the age of 58 years. He was graduated from Hahnemann Medical College and Hospital of Pennsylvania in the class of 1890.

Dr. William H. Bennett died at Atlantic City, N. J., May 14, at the age of 76 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1869. He was for twenty-five years physician to the Seashore Home for Invalid Children; founder and president of the Mercer Memorial Home for Invalid Women; founder and president of St. Christopher's Hospital for Children, Philadelphia; consulting physician to Widener Memorial Home; a member of the Philadelphia Pediatric Society, the Pathological Society of Philadelphia, the Medical Society of the State of Pennsylvania, and a Fellow of the American Medical Association.

Dr. Ralph MacClay Lashelle, formerly of Centralia, Pa., died at Media, Pa., on May 20, at the age of 77 years. He was graduated from Jefferson Medical College in the class of 1888.

Dr. John A. Donovan, a graduate of New York University Medical College, in 1866, and for 53 years a practitioner of medicine in Lewiston, Me., died in that city, about May 25, aged 78 years.

Correspondence.

OF INTEREST TO MEDICAL LIBRARIANS.

To the Editor of the Medical Record:

Sir:—There has accumulated in the Surgeon General's Library a considerable amount of material in the way of duplicate medical books and periodicals. Owing to lack of space, much of this material will have to be condemned and disposed of. In accordance with the policies of the library, a free access to all medical literature in duplicate has been given to the medical libraries of the country, the only condition being that they remove the material at their own expense. Those in charge of medical libraries not too far away from Washington, D. C., may take advantage of this opportunity for adding to their collections or supplying their desiderata until September 1 of this year.

Francis A. Winter,
Colonel, M. C., U. S. A.,
Librarian, S. G. O.

Washington, D. C.

THE SALE OF ALCOHOLIC DRINKS.

To the Editor of the Medical Record:

Sir:—Regarding the unlimited sale of alcohol, I wish to make the following remarks: The prohibition question has aroused so much discussion, pro and contra, in the medical as well as in the lay press, as perhaps no other question for a long time. When the new narcotic law was passed there was no noise about it, except, perhaps, some dissatisfaction of a number of physicians or druggists with the bother or the extra registration fee; otherwise everybody felt that something had to be done to check the evil that ruins the health of the addicts, and we did not hear any complaints about alleged interference with the people's personal rights. Why? Is it because this is a "drug" and the other is a "drink"? But it is not the name that interests us, it is the article, and there are two sides to the question of both narcotics and alcohol; both are beneficial if used when indicated and in the right dose, and both are harmful when abused. The claim that the prohibition law interferes with the personal rights of the people is, in my opinion, scientifically absurd. Alcohol ruins not only the health of the addicts, both physical and mental, and makes them a burden to the community (besides its ruinous influence on the family), but it also has, as we all know, a harmful influence on the descendants, and they (the addicts) surely have no right to bring into the world demented and otherwise physically and mentally crippled offspring, nervous wrecks, degenerates, lunatics, epileptics, etc. Is this what the antiprohibitionists call "interference with the people's personal rights?" They may say, why should they be deprived of it in a *moderate*, not harmful quantity? It is true that it is not so very hard to define the "moderate, not harmful" quantity, but how would the antiprohibitionists control the sale of it in order that it should not be abused? There has been found a way to prevent the abuse of narcotics; but how do the antiprohibitionists think to manage with alcohol? If they know of some ways and means to prevent its abuse and keep the sale of it under control, let them speak and let us hear; we shall gladly accept their proposition if possible—otherwise it is to be condemned.

Dr. H. Rabinowitsch.

432 West Thirty-fourth Street, New York.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, May 16, 1919.

Women and the Medical Society of London.—The most interesting event of the medical week in London was the annual meeting of the Medical Society because at that meeting the question of the admission of women to full membership of the Society was discussed in some detail. In the discussion all the old arguments for and against, every one of which has some logical flaw or another, were trotted out, and in the end the bar to women against full membership was maintained. It is over 30 years since a by-law of the Medical Society of London made it inadmissible for women to be Fellows of the Society, the step having been taken when it first became evident that women intended to adopt the medical profession as a regular career. There is no doubt that there was at that time in London, almost as much as in Edinburgh, a feeling that women were intruding upon a sphere for which they were ill-fitted and the Medical Society in its action was registering the professional spirit of the day. But as all such feeling against the female practitioners in medicine appears to have completely passed away from the minds of the present generation, especially from the minds of its younger representatives in the medical profession, it is a little puzzling to learn that the Medical Society should have decided to maintain its old position. In fact, it is probable that the old position was only maintained by the actual voting power of the older men among the members. The resolution which was brought forward by the Council of the Society to delete the law excluding women was not as a matter of fact put to the vote because an amendment, which took its place confirmed the existing right of women to be present at the meetings. The amendment was not accepted in place of the substantive motion, and there is little doubt which way the voting would have gone if the original motion had been pressed to a division: the amendment was merely used as a reason for delay in coming to a conclusion. The arguments against the admission of women to full membership can be summed up as two-fold, the conservative one and the social one. The conservative members of the Medical Society adopted the argument that Lettsom when he founded their body did not contemplate the admission of women, and while this point is granted to them they must on their side concede that they have not the least idea what Lettsom's opinion on the subject would have been if the contingency had arisen in his lifetime. The social argument is that the Medical Society of London has always been a sort of medical club for male doctors, has enjoyed prosperity and prestige in this guise, and therefore should not be changed. There is something to be said for this argument

also and something to be said against it. For it there is the obvious truth that members of a club have the right to include in and exclude from their own club whomsoever they like, and this position can be taken up by the Medical Society with some strength, for there is in existence in London a medical society the membership of which is confined to women. Such were the feelings that prevailed at the meeting and that dictated the voting. But surely the more thoughtful members of the Medical Society of London will see that they are placing their institution on a low plane by regarding it simply as a club. On the other hand if it is to be regarded primarily as a learned society existing for the collection and diffusion of scientific knowledge it is clear that in these days the members are acting in a short sighted manner to exclude women. Delay may bring better counsel.

Tuberculosis Sanatoria for Discharged Soldiers and Sailors.—The president of the local Government Board and the Minister of Pensions have combined to carry through a piece of work whose urgency is undoubted. It is almost incredible that as yet no proper organization exists for the provision of sanatoria for the reception of soldiers and sailors discharged as suffering from tuberculosis. The two presidents have now appointed a committee "to consider and report upon the immediate practical steps which should be taken for the provision of residential treatment for discharged soldiers and sailors suffering from pulmonary tuberculosis and for their re-introduction into employment, especially on the land," and in the last few words lies its greatest promise of good. French experience in relation to their tuberculosis infected soldiers, as well as the reports of farm colonies for the tuberculous in many countries, have proved that while the tuberculous man tills the soil he heals himself in a substantial proportion of cases.

The Radium Institute.—This institute has been working quietly and steadily throughout the war, supported by a good financial endowment but much hampered by the difficulty of obtaining scientific assistance on the staff, the needs of the Army and Navy having absorbed all the available pathological talent of the country. The report for the past years' working, bringing the record up to the beginning of 1919 announces, however, the establishment of a pathological laboratory in connection with the Institute over which Dr. J. C. Mottram, a well-known worker at the Cancer Department of the Middlesex Hospital, has been appointed. This is a step not only in the right direction but in the only direction in which progress lies as far as the therapeutic use of radium is in question, and it is made in full accord with the nature of the last report of the Institute, now issued by the Director, Captain Hayward-Pinch, F. R. C. S. Public opinion, and unfortunately medical opinion, seem to have decided that the value of radium in medicine is commensurate with its practical results in the treatment of cancer, whereas such a limitation is entirely wrong. First, the employment of radium is neither the best nor a specific cure of cancer, for a large percentage of malignant manifestations are better dealt with by operation, and a substantial percentage of these manifestations, though inoperable, are also not amenable to radium treatment. Secondly, radium is of great value in many forms of obstinate skin disease, in many varieties of benign tumour and in such scourges of women as uterine fibroids and chronic metritis. The last report of Captain Hayward-Pinch leaving the use of radium in cancer aside, dwells especially upon its use in the numerous other conditions, and with this developing employment of a new and drastic remedy there should certainly go, and go hand-in-hand, laboratory investigation into all the chemical and physical circumstances which attend the treatment and make up the pathological story. Following upon intensive investigation of this sort we ought to get valuable information. Much of the work done at the Radium Institute is entirely gratuitous, some 65 per cent of the patients making absolutely no payment. This is good hearing for charitable ears, but the middle-class and the wealthy get sick as well as the poor, and radium is not available for their treatment at the present moment. With a spread in the scientific world of the knowledge that radium has many more uses than are implied in the treatment of cancer we may expect some organized plan to arise whereby supplies of radium can be placed at the disposal of the medical profession, through the Radium Institute, and upon some really orderly plan.

The Lords and the Quacks.—The Ministry of Health Bill is now under discussion of the House of Lords where the second clause dealing with the powers and duties of the Minister are being discussed in Committee. Lord Bledisloe, better known as Sir Charles Bathurst, had already promised to move a new clause giving the Minister of Health power to institute any necessary proceedings to enforce compliance with the laws relating to the sale and advertisement of any patent secret or proprietary remedy or appliance. Later on the same broad-minded senator moved an amendment which would give the Minister of Health power to take measures for the avoidance of fraud in connection with alleged remedies for the cure of diseases. No one is better fitted to bring forward such an amendment than Lord Bledisloe for it was on his initiative that a Select Committee of the House of Commons was set up in 1912 to investigate the whole question of patent and proprietary medicines. The report of that Committee was presented, as it happened, on the very day of the outbreak of war, and it opened the eyes of the public to a fact with which the medical profession was perfectly familiar, namely, that a large band of quacks were engaged in a deliberate attack against the wellbeing of the nation, preying upon the weaknesses, especially the sexual weaknesses of mankind, claiming to cure incurable diseases, and in this way not only swindling their victims out of money but depriving them of the chances of cure by scientific methods which would have been theirs, had they taken the mischief in hand in time. The amendment for the moment was not accepted but the feeling of the House on the matter may be gauged by the fact that Lord Buckmaster, an ex Lord

Chancellor, said that it was impossible to overrate the importance of the questions raised. He added that a cursory glance at the report of the Select Committee was sufficient to show that at the present moment this country was at the mercy of a gang of people who in many cases were quite destitute of honor or scruple, and who were busily engaged by fraudulent or dishonest means in vending drugs and food that in many cases were absolutely dangerous to the health of the people by whom they were consumed. It was quite plain that the present remedies were ineffectual, and one of the reasons why they were so was that they never knew the Department upon whom the duty of taking action depended. The government for the moment do not wish to place the definite duties postulated by Lord Bledisloe's amendments upon the shoulders of the Minister of Health, lest this infant official should be asked to carry too big a burden immediately after his birth. But the medical profession say that it was precisely to look after the health of the people, and put down such scandals as those dwelt on by Lord Buckmaster, that the Minister of Health was ever born; if he cannot discharge such a public function as the protection of the people against the quack, what has he been born for?

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

PARIS, April 27, 1919.

The International Congress at Cannes.—The conference at Cannes of British, American, French, Italian, and Japanese Red Cross Societies has been considering the reports of the subcommittees on tuberculosis and malaria. The tuberculosis subcommittee report makes several recommendations, including the regular inspection of school children with a view to early detection of the disease and popular propaganda by all suitable means. The establishment of open-air schools for children already infected or suspected of tuberculosis is recommended and also the extension of the open-air system to all institutions of segregation such as barracks, asylums, orphanages, and workhouses. The committee approved of the compulsory notification of tuberculosis to the health authorities.

Malaria.—In the deliberations of the malaria subcommittee five of the world's greatest experts have taken part, Sir Ronald Ross; Dr. Laveran, discoverer of the parasite of malaria, Paris; Professors Marchiafava, University of Rome, Golgi, President of the Italian Board of Health, and Bastianelli, of Rome. Dr. Laveran presided and congratulated the conference on placing the fight against malaria side by side in importance with humanity's fight against tuberculosis and venereal disease. The committee recommended popular propaganda on a great scale for instructing the public as to the steps needful to combat the disease. The problem is one of peculiar interest to the British Empire on account of its far-flung colonies. In the case of Italy and other countries it is a domestic problem. The suggested propaganda is to include illustration of antimalarial measures by charts, photographs, and kinematograph records and also of an intensive campaign against mosquitos. Dr. Laveran referred to the great part school teachers can play in combating disease and gave as an illustration Corsica, where schoolmasters successfully have explained the steps to be taken to children, who in turn instruct their parents. A special tribute was paid to the great work Sir Ronald Ross had done in helping humanity to discover the part the mosquito plays in carrying infection. The committee recommended the immediate establishment of an international malarial bureau in conjunction with the suggested league of Red Cross Societies.

Nursing.—Many women delegates were present when the report of the Nursing Committee was presented to the conference by Miss Julia Stimson, chairman and director of the Nursing Service of the A. E. F., and the British delegates on the committee, Miss Lloyd, matron of St. Thomas' Hospital, London, and Miss Gill, matron of the Royal Infirmary, Edinburgh. The committee suggest the organization of a special nursing department in the central Red Cross bureau to act as a clearing house of ideas in all nursing and health work. The utmost importance was attached to the great army of volunteer workers, the V. A. D.'s in England. Dr. Welch of Baltimore referred to the fact that many new careers in public health work will be offered to women, and that they must inevitably perform the major part of the work in the world health campaign now being organized. At the conclusion of the conference a unanimous vote of thanks and appreciation was passed to all nurses who have so nobly served their countries and the armies of the Allied nations.

Child Welfare.—Several speakers in discussing the report of the child welfare subcommittee, urged the need of concentrating attention on the prenatal period, and the necessity of legislation in industrial centers forbidding mothers from working for three or four months before childbirth. Much greater attention, it was urged, should be given to the education of the child at school on health matters. Sir Arthur Newsholme said venereal disease was responsible for much ill-health in children and the seeds of tuberculosis were generally planted in childhood, therefore the purpose of the Child Welfare campaign was closely related to these two subjects. Dr. Truby King, of New Zealand, drew attention to the appalling state of the children's teeth, and referred to the subject as an almost universal disease. He maintained that with due antenatal and postnatal care the teeth question could almost be solved without the use of tooth brushes. Dr. Biggs of New York referred to the plan which he said had been successfully operating in New York for the past year by which all marriages must be notified to the authorities. Three months subsequently the health authorities send a circular letter to every young married woman drawing her attention to special information on the problems of childhood which is at her disposal.

Prostitution.—Professor Duerey, of the University of Pisa, said the program regarding the regulation of prostitution by government is now being prepared in Italy and will be completed in a few weeks. He favored the control of the sale of alcohol and of drugs as being closely related to the spread of disease. He believed that measures for the abolition of all official regulation and tolera-

tion of prostitution would not be possible in some countries, and each country must act for itself. Colonel L. H. Harrison of the British Army said that in the British Army in 1885, 320 out of every 1000 admissions to hospital were due to venereal disease, while in 1913 these had decreased to 51 per 1000, although in that time no propaganda against the evil existed and prophylaxis was not part of the British Army regulations. The remarkable reduction, he considered, was due to improved social conditions, suitable entertainments, and occupations in the leisure moments of the men. Colonel F. F. Russell, U. S. A., said there was the greatest necessity at this time for an energetic Government campaign because of the demobilization of armies. Through Red Cross societies there were means of carrying the lesson and influencing public opinion. Colonel Cummins, of the British Army, urged standardized regulations in dealing with prostitution. Dr. Biggs and Sir Robert Philip advocated a closer and more definite terminology in discussing these subjects and suggested that each malady should be called by its name and not grouped under the head of venereal diseases. In that way the education of the people was easier. Professor Marchiafava said all immoral literature and pornographic books should be suppressed by law.

Dr. Rist of Paris said he believed that the opinion was growing for complete abolition and suppression of all official regulation and tolerance of prostitution and that this sentiment is growing in countries even where prostitution has been tolerated heretofore. Professor Kabeshima, the Japanese delegate, said that the question of suppression of prostitution in Japan was delicate and difficult, but at the present time there was a movement to make regulation and inspection more strict and eliminate clandestine prostitution and street traffic of women.

5. The Clinical Picture of Streptococcus Viridans Infection.—Heinrich F. Wolf draws attention to the importance of the clinical picture and the danger of blind reliance upon laboratory methods of diagnosis. He says, "Ten or twenty years from now people will not go to a physician, but to a laboratory. In the diagnostic clinic they will be examined by specialists, they will know every deviation from the normal, but nobody will know what is ailing the patient and how he should be treated." For the sake of brevity the author confines his remarks to the rheumatic manifestation with exclusion of endocarditis, and points out that infection with the *Streptococcus viridans* is the most frequent cause, but not the only one; the type of infection may be indicated by the clinical picture. It should be remembered that infectious foci can exist in the body without causing any symptoms, and that abscesses in the teeth and tonsils may be found without giving rise to a systemic infection. That a systemic infection may be present in spite of a negative biological reaction and that a positive biological reaction, for instance a positive Wassermann or a positive gonococcus complement fixation test, is no proof that a given disease is of the etiology which is indicated by the test. The number of patients who are treated with gonococcus vaccine for a rheumatic infection and whose disease has nothing to do with that infection is very large. The value of the clinical picture in determining the etiological diagnosis of the so-called rheumatic diseases has been grossly underestimated. The author also points out that as the clinical picture is due to the reaction of the body tissue against the invading and attacking organism we may expect the clinical picture to vary according to the type of the organism. However, the differences in the clinical picture are not always pronounced, but they are distinct enough to allow of a differentiation, and the fact that this has been overlooked can probably be attributed more to the dulling of our clinical eye and sense than to the lack of clear indications. We must not forget that a clinical picture may be due to a mixed infection, and that each infecting agent leaves its trace in the appearance of the disease. Wolf adds that the clinical material at his disposal is not large enough to work out a clinical picture for every type of infection. His object is to awaken interest in the subject, to give to the clinical picture the importance it deserves, and to get away to some extent from the tyranny of the laboratory.

7. Mental Deficiency in Prostitutes: A Study of Delinquent Women at an Army Port of Embarkation.—Paul A. Mertz presents some data on the mental status of a group of delinquent women examined at Newport News, Va., under military direction. The women examined came from all parts of the Eastern and Southern States; many were the wives of soldiers, others were women attracted to Newport News as being the port of embarkation and, later, debarkation for the American troops. The results are all the more important, therefore, in that they may be considered as being national rather than local. The mental examination of women arrested for prostitution and similar offenses was begun early in July, 1918, by Major Earl D. Bond, port of embarkation psychiatrist, and was continued by the author, who assumed psychologic duties in November. A physical examination to determine the presence of venereal disease and a psychologic examination were given in every case. Very few of the women were professional prostitutes. Of the white women, 62 per cent. were married, many of them to soldiers. Approximately 74 per cent. of the white women and 79 per cent. of the colored women were found to be infected with a communicable venereal disease. The Binet-Simon (Goddard revision) mental examination was made in 126 cases; the author points out that this test was used rather than the newer Stanford revision by Terman's method for the sake of uniformity. He sums up the results of his observations as follows: (1) Fifty-three per cent. of the women arrested for prostitution and kindred offenses and held in the detention home for examination had a mental

age of 10 or under. (2) In addition, 15 per cent. of those who were not mentally deficient showed mental disorder. (3) Ten per cent. were so deficient as to warrant, under existing laws, segregation in an institution for feebleminded. (4) Fifty per cent. of these women did not reach the fifth grade in school. (5) If a "type" is being sought, it might be said that the composite of the delinquent woman as found in Newport News would seem to be a woman of 19, slightly mentally deficient, with schooling to the fourth grade. Upon comparing his results with similar data obtained elsewhere, the author points out that the percentage of feebleminded is approximately the same; that is, his figures add evidence to the belief that virtually half the country's prostitutes are mentally deficient or feebleminded. He lays emphasis on the importance of accumulating data of this sort as the country may thereby be brought to realize the necessity for legislation to restrain the prostitution of high-grade morons who appear to the uninitiated perfectly normal, and who are often unusually attractive physically.

1. A Lecture on Missiles as Emboli.—Sir John Bland Sutton cites a number of cases in which missiles have attained more curious places by accident than they could by design. In 1834 Thomas Davis reported the case of a boy of ten who made a gun of a telescopic toasting fork. To form the breech of the gun he drove a plug of wood 3 inches into the hollow handle of the fork and made a touch hole. When the gunpowder exploded the stick was forced into his chest between the third and fourth costal cartilages, to the right of the sternum. After death, which occurred 37 days after the accident, a piece of wood 3 inches long and as thick as a cedar pencil was found in the right ventricle of the heart, encrusted in clot. Davis was of opinion that the stick, after wounding the lung, passed into the vena cava and was carried by the blood stream into the right auricle, and then into the right ventricle; the word embolus was not coined until at least a quarter of a century later. Another early record is that of a soldier who, after the storming of the Great Pagoda, Rangoon, in 1852, received a round leaden bullet between the third and fourth ribs, near the anterior fold of the left axilla. Blood and air issued from the wound for several days, and the surrounding tissues became emphysematous. Death occurred 72 days later. A pint of pus was found in the left pleural cavity, and a piece of cloth from the man's jacket. The lung was solid. The track of the missile ran through the chest to the left pulmonary veins. The rifle ball lay in the left ventricle of the heart, near its apex. There was no wound of the heart. It appeared, therefore, that the ball perforated one of the left pulmonary veins, entered the left auricle, and finally passed into and settled in the left ventricle. Since 1896, when Farina, of Rome, stitched a stab wound of the heart, gunshot and incised wounds of the heart have attracted much attention, and the war has furnished many remarkable examples of the manner in which missiles enter and leave the heart, and instructive preparations illustrating such accidents are comprised in the War Office collection of pathological specimens. In one case there was a hole in the right side of the chest, in the right leaf of the diaphragm, and in the inferior vena cava 2½ cm. below the place where the hepatic vein joins the caval vein. A flat piece of shrapnel, 2 cm. square and 12 mm. thick, lay in the right ventricle of the heart. There was no wound of the heart. The piece of metal, after piercing the chest wall and the diaphragm, entered the inferior vena cava and the blood current transported it to the heart. The clinical history did not suggest any hampering of the action of the heart. The man died from severe streptococcal infection. In another specimen a fragment of metal is detained among the cords of the tricuspid valve. The soldier was wounded in the liver. There is a hole in the hepatic vein, through which the missile reached in turn the vena cava, the right auricle, and the right ventricle. The movements of shrapnel bullets in the cavities of the heart can be made visible by radioscopic methods. One in the right auricle performed whirling movements in an elliptic orbit with a major axis of 2 cm. (Barret); another observed by Ledoux-Lebard in the right ventricle *s'agitait comme la bille d'un grelot.* Lobligeois detected a shrapnel ball in the left ventricle and watched its motion. In diastole the ball rested near the apex of the heart. During systole it slipped rapidly to the right, struck the septum, rose in the ventricle, remained still for an instant, and then descended slowly during systole, till it reached the position near the apex of the heart, from whence it started. The movements occurred with great rapidity. A bullet in the right ventricle may be ejected and produce fatal pulmonary embolism. This happened in the case of a soldier. A German bullet entered the left external iliac artery and penetrated the adjacent iliac vein. It was carried by the blood current along the big veins to the heart, was ejected from the right ventricle and plugged the left pulmonary artery. Or a missile in the left ventricle may be driven into a systemic artery and produce ischemia. A boy, aged 18, shot himself in the heart with a 7-mm. revolver. There was shock for some hours and the next day pain in the right arm, which presented signs of ischemic paralysis, and the bullet could be felt in the axilla. Ten weeks later the bullet was excised from the axillary artery, the vessel above and below the bullet being occupied by clot. The ischemia slowly disappeared. As the boy recovered, the exact route of the bullet cannot be stated, but it is probable that it penetrated the chest, the wall of the heart, and lodged in the cavity of the left ventricle; it was then expelled as an embolus through the aorta, innominate and subclavian arteries to be impacted in the axillary artery. O'Neill had an opportunity of actually localizing a missile in the left ventricle radioscopically and subsequently finding it in the common iliac artery. Missiles may also enter a large artery and behave as emboli without entering the heart. A soldier received a rifle bullet wound in the chest. Four pints of effused blood were evacuated, and the wound sewed up. Streptococci were obtained in culture from the effused blood and the man died on the fifth day. Before death a bullet could be felt in the left external iliac artery. After death a small wound was found in the aorta just below the arch; this was the place of entry, and the bullet was driven as an embolus along the aorta into the iliac artery. Each end of the bullet was embedded in firm clot. In the Napoleonic wars a case occurred in which a bullet entered the side of the chest. The man, an English sailor, survived three days. At post mortem it was found that the ball, which measured 1¼ inches in circumference, had penetrated the first part of the aorta and lay within its lumen, embedded in clot. The hole in the wall of the aorta was partially closed by a plug of skin and fat carried in by the ball. To show that penetrating bullet wounds of the aorta are not always fatal, the author cites the case of a Westphalian miner who attempted suicide. The bullet entered the left side of the chest, near the seventh rib. There was no disturbance of the heart's action, and radioscopic examination failed to furnish evidence of the bullet. An effusion in the left pleural cavity disap-

peared in a few weeks, and the man recovered. Thirteen months later he was killed by an electric current in the course of his occupation, and the bullet was found in the aortic sinus, attached to the wall by a slender pedicle.

9. Subacute Trench Fever.—J. H. Lloyd points out that though a great deal has been written on the acute form of trench fever, its existence in a subacute form has not received the attention it deserves. Colonel R. D. Rudolf has suggested the term "trench fever cachexia" for the subacute cases; in the author's opinion this term gives undue prominence to one only of the many concomitants, and that one is not always present, and for this reason Lloyd prefers the name "subacute trench fever." The temperature in such cases is quite unstable; it usually keeps below 98° to 99°, but is unsteady and the man's sufferings will be found to correspond closely with his temperature. The diurnal variation most days will be 2°, and sometimes 3° or even 4°. At other times the curve will shoot up to 102° or 103°, and fall again to 96° or so, all in a few hours. This Major Lloyd describes as a "low-geared pyrexia." In these cases the spleen should be examined by percussion as well as by palpation, as probably more cases show a non-palpable splenic enlargement. When enlarged the organ is more or less constant in size. The author states that he has had no opportunity of examining the areas of hyperesthesia noted by Carmalt Jones; nor has he seen the maculae which occur in the acute fever. He divides cases into the two following symptom groups: (1) The painful group, which includes cases diagnosed as rheumatism, myalgia, neuritis, etc. Patients complain of aches and pains in different parts of the body, and in many cases there is no history of an original definite acute attack. (2) The debility group, which includes at one end the men whose chief disability is the "effort syndrome" and who are sent to hospital as D. A. H. and V. D. H. cases, and at the other end men complaining of being "done up," "nerves all gone," and "depression," the diagnosis being "N. Y. D. N.," "neurasthenia," "debility," etc. The author believes that D. A. H. will prove to be an expression of the fever and not a sequela, and that in the N. Y. D. N. cases the symptoms are produced more by the fever than by shell fire. Out of a total of 400 of these latter cases the author found an average at any one time of about fifty cases of trench fever, either acute or subacute. Many of these cases come into hospital with a note to say "fainted" or "collapsed under heavy shell-fire." Their previous history will generally show that they have been suffering from trench fever for some time previously. In such cases the smoldering fever is likely at any time to flare up into a flame and life in the line probably helps to bring about the exacerbation. If this happens suddenly the man collapses. The pyrexia of 102 or 103 deg., however, may last but a very few hours, and when the man is seen by the medical officer the temperature may again be normal or below. What exactly determines the groups of symptoms is not known, unless it be the stress of the poisoning, the susceptibility of the various tissues, and the man's own psychology. It is possible also that the virus of trench fever may be a cause of some cases of war nephritis; if this is so we shall have a third group—the nephritis cases, and the author points out that it will probably be in the comparatively difficult-to-recognize subacute form that most of the mischief will have been done. He remarks that when we know more about trench fever in its acute and subacute forms, it may be interesting to draw comparisons between this disease, syphilis, and malaria. It might also be of interest to compare temperature charts in the subacute phases of these three diseases. A point to be remembered in connection with this subacute form of trench fever is the possibility of regarding a man suffering from this condition as a malingerer. It is also important that the condition should be recognized by members of boards examining and reporting on the condition of men about to be discharged from the army.

Insufficient Left Kidney and Right-sided Nephrectomy Followed by Successful Result.—H. Kümmell studies the operative treatment of certain bilateral renal changes. The best guide in these complex processes is the control of the urinary concentration. The case which the writer reports in full was that of a female, aet. 49 years, with tuberculosis of the right kidney and a colon bacillus nephritis of the left kidney. The freezing point of the urine was 0.62°. The first operation was decapsulation of the left kidney, following which the urine from that organ improved, the albumin and casts disappeared, while the cryoscopic index fell to 0.58°. Five weeks after the decapsulation the writer performed a nephrectomy of the right kidney. The successful outcome was complete, the freezing point became normal, likewise the quantity of residual nitrogen in the urine.

Treatment of Diseases of the Blood and Injections with Protein Bodies.—Dollken has extended the domain of therapeutics of diseases of the blood by resorting to the use of milk injections and other more determinate protein bodies. In hemorrhagic purpura the action of milk on the liver and small vessels is excellent. The blood coagubility increases after the injection with an astonishing rapidity. In infectious diseases with mild albuminuria, milk injections cause the urinary albumin to disappear permanently. In three cases of Weil's disease the effect of milk injections was very rapid, likewise their effect on the liver made manifest by a diminution of the icterus. On the other hand, the general and nervous symptoms were not influenced. The disease, regardless of this treatment, may continue its evolution for several weeks, although the hepatic symptoms do not reappear. In dysentery the effect of milk injections is favorable. The agglutination index does not increase, thus offering a larger field for more specific therapeutics.

Bacteriological and Serological Essentials for the Prophylaxis and Treatment of Gas Edema with a Polyvalent Serum.—F. Klose establishes three groups of pathogenic agents of gas edema, viz., (1) The immotile butyric bacillus; (2) the motile butyric bacillus, and (3) the motile *Bacillus putrificus*. These three organisms described in the literature are classified by the writer under the above headings. The various anti-gas edema sera have shown unequal powers against these various pathogenic agents and for this reason the writer has attempted to prepare a serum by injecting horses with the three types of bacilli. His experimental results, from the viewpoint both of prophylaxis and of treatment, have been satisfactory. In human surgery the data so far obtained regarding this serum are insufficient. The writer only expresses the opinion that surgery has found a powerful aid in the treatment of gas edema, and that in no case surgical treatment, properly speaking, should be neglected or subordinated to treatment by the serum.

A Case of Polycythemia Treated Successfully by Radiotherapy.—G. Mönch has observed a case of polyglobulia in a woman aet. 52 years, a XII para, who suffered from frequent hemorrhages. Red blood corpuscles, 7,480,000; hemoglobin, 170 per cent. irradiation was made not only over the spleen, but especially over the long bones. The writer is of the opinion, and correctly so, that *x*-ray treatment of the spleen alone overlooks the site of essential production of the red blood corpuscles, so that the rational treatment should be, above all, directed to the bone marrow. In this case there were three séances in all, the second being eight weeks after the first, the third four weeks after the second. The objective and subjective symptoms disappeared. Red blood corpuscles 4,800,000; hemoglobin 90 per cent. This amelioration was still complete three months after cessation of the treatment. The white cell count remained absolutely stationary at 5,200 during the entire treatment.

Tissue Regeneration in Man.—A. Bier in this, his nineteenth contribution to the subject, considers regeneration of the joints and the mechanism of some of

their morbid changes. For example, ankylosis is greatly favored by constant pressure, bringing the component parts of the joint against each other, an important fact to be remembered when treating pseudoarthroses or in the operative reestablishment of joint movements. As to intraarticular movable bodies, Bier offers an interesting explanation. The synovia possesses an osteolytic action which comes into play as soon as the joint lining has become the seat of some lesion. This action may erode the bone irregularly and end in separation of some bits; these becoming free in the joint, while at their point of attachment a thin layer of cartilage may form. The writer explains by this theory how certain intraarticular bodies may increase in size. This occurs when they become surrounded by a layer of protecting cartilage. Bier has been able to observe, during operations on the joints, a superficial regeneration of the cartilage. This takes place at the borders of the solution of continuity, just as the epithelium proliferates on the edges of a cutaneous lesion. The synovia is the feeder of the cartilage *par excellence.* What becomes of blood collections in the joints? It is inexact to maintain, as do some surgeons, that the blood remains in a fluid state. Bier has seen thick clots from within an hour or two following hemorrhage into a joint. After four or five hours the clot is smaller and a bloody fluid is also present. This latter can be withdrawn by puncture, from which has arisen the erroneous opinion that the blood remains fluid. This fluid is nothing but the product of dissolution of the intrasynovial clot. The ankylosing action of infections may frequently be due to disappearance of the synovine, but in mild inflammatory processes this substance persists and prevents the development of an ankylosis as it maintains the shape of the joint against the inflammatory process. Bier does not lose the opportunity for referring to his venous stasis in referring to gonorrheal arthritis. The intense sensitiveness of these lesions can be easily overcome by this treatment so that systematic mobilization may be carried out, thus preventing ankylosis. Finally, the writer reports some astonishing cases of regeneration in advanced tuberculous arthritis, which seem too good to be true.

The Reactions of Antituberculous Immunity in Influenza.—M. Berliner has been able to note in cases of influenza a persistence of the antibodies against tuberculosis. Cutaneous reactions to tuberculin had disappeared. The paper continues with a long, uninteresting theoretical discussion.

Deutsche medizinische Wochenschrift.

March 6, 1919.

Regeneration of Joints.—A. Bier discusses the possibilities of regeneration of tuberculous joints and appears to have an astonishing amount of optimism. He is of opinion that immobilization in the treatment of these lesions has been greatly exaggerated and he pretends that he has obtained successes which "exceed anything that has so far been attained in this domain," by carrying out the following treatment in cases of coxalgia. Plaster casts he banishes; extension is reserved for cases of contracture or subdislocation; insolation overcomes the pain within one to two weeks, after which methodical and prudent mobilization accomplishes the rest of the cure. Hemorrhage into a joint cavity is a real "poison" for the articulation; the blood provokes partial destruction of the structures, contractures and ankyloses; spontaneous absorption is extremely slow and therefore puncture should always be resorted to in hemarthrosis. The admixture of blood with crushed tissues possesses a marked cicatrizing action, while a mixture of blood and bone marrow has a strong osteogenic action.

The Salvarsan Question.—A. Dührssen appears to be starting a war against this supposed specific of syphilis. He insists particularly on the incapacity of a commission recently appointed to formulate the maximum dose of salvarsan. He opposes certain writings of von Wassermann and other "promisers of rapid cures," and brings forward contrary opinions in which the impossibility of declaring as cured a case of syphilis treated by salvarsan is maintained. The writer even suspects that the enormous advertising that 606 got in the daily press has been the means of causing an enormous diffusion of lues by leading the public to suppose that they can be readily cured if infected. In Germany during the years 1910 to 1914 there were 120,000 cases of syphilis treated in hospitals, whereas during the same number of years previous to the advent of salvarsan only 50 per cent. of that number of cases were admitted.

March 22, 1919

Grippe Otitis in 1918.—Farner appears to believe that the old pandemic of 1889-91 became relatively innocuous until, after the expiration of nearly a generation, it underwent a recrudescence. Throughout this entire period the ear has been menaced. In the nineties influenzaotitis was a frequent diagnosis. This was natural, for during the pandemic years its frequency was apparent. This disease association appeared slowly to fade away and at the début of the last pandemic, and often throughout its entire course, the per cent. of ear disease was insignificent. But while the incidence is very low, there is nevertheless a small percentage of cases of ear disease in the present pandemic, and the cases agree very closely in all but frequency with influenzaotitis in 1889-91. To give some idea of relative frequency in the old pandemic, the normal percentage of otitis was increased from three to as high as thirty-fold, according to the clinic. A general average was difficult to obtain. In the recent pandemic the statement current is that about 3 per cent. of all grippe patients presented ear complications at the outside. A comparison seems difficult to institute, but clearly the recent pandemic spared the ears else we should have seen, had the proportion been abreast of some other complications, much deafness as well as fatal ending. A peculiarity of the last pandemic was the very small incidence of neuralgias and nervous deafness in comparison with the predecessor. In other words, we have a fairly constant type of organic grippe otitis characterized, save in empyema cases, by a rapid and benign course. During July to December the author treated 115 cases of grippe otitis, the majority being males in the best years.

Prevention of Certain Migraines.—Pagniez, Vallery-Radot and Nast emphasize the relative hopelessness of a prophylaxis of sick headaches but believe they have struck a clue to the nature of one type of this affection which may admit of control in advance. They report 5 cases of migraine the first of which is in part as follows: The patient naturally sound but of a migrainous family and affected by myopia and astigmatism had suffered from migraine since the age of 10 years and was now 34. However, at the age of 20 he had obtained notable improvement by going upon a vegetarian diet. At 31 he went back to a protein regimen and at once suffered in the original degree and worse, a *status hemicranicus* developing at one time. The vegetarian diet seemed to have lost its efficacy. In addition he began to suffer from indigestion and constipation, which apparently had originally been absent. Upon a theory based upon sensitiveness to foreign protein the authors began to give the patient small doses of peptone, having learned that in giant urticaria of enteric or food origin this principle is of value. The result was startling, for half a gram before meals during the intervals produced an almost abortive effect. After virtual freedom for some weeks the peptone was suspended and the migraine returned, but in a mild type. Six months later, however, the affection became more severe and the peptone was resumed for a short time. When it was again withdrawn the patient not only remained free but was able to eat freely of meat and eggs. The small doses of protein had apparently removed an anaphylactic tendency, or in other words, were anaphylactic. Of the other 4 cases cited all were of the same type dating from early years, severe and inveterate, unresponsive to treatment and with a tendency to indigestion. All were benefited in the same manner by peptone.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

VICTORY MEETING.

Seventieth Annual Session, Held in Atlantic City, June 9, 10, 11, 12, and 13, 1919.

HOUSE OF DELEGATES.

First Day—Monday, June 9, 1919.

THE SPEAKER, HUBERT WORK OF PUEBLO, COL., IN THE CHAIR.

AFTER the adoption of the minutes of the last meeting and brief addresses by the Speaker of the House, the President, Dr. Arthur Dean Bevan, and the President Elect, Dr. Alexander Lambert, the following reports were presented.

Report of Secretary.—Dr. ALEXANDER R. CRAIG of Chicago submitted this report, which showed that the membership of the various constituent State associations which constituted the membership of this Association, according to the records in the Secretary's office, May 1 1919, was 82,288. The Fellowship of the American Medical Association on May 1, 1918, was 44,715; on May 1, 1919, it was 45,412, a net increase for the year of 697. During the year Dr. Ludvig Hektoen of Chicago had tendered his resignation as a member of the Council on Health and Public Instruction, and the President appointed Dr. Victor C. Vaughan of Ann Arbor, Mich., to serve on this Council until this annual session. Dr. H. Gideon Wells of Chicago tendered his resignation from the Council of Medical Education, and the President appointed Dr. John B. Dodson of Rochester, Minn., to fill the vacancy until this annual session. Dr. H. D. Arnold of Boston also resigned from the Council on Medical Education, and the President appointed Dr. Isadore Dyer of New Orleans to fill the vacancy until this annual session. This report stated that during the progress of the war reports had been submitted to the House of Delegates regarding the Association's cooperation with the Federal Government in matters involving the service of physicians. The Association endeavored to assist the Government in every way in which this could be done by a civilian organization. A review of these war activities revealed few, if any, instances where the Association could have done more or acted differently than it did. However, in mobilizing an army under the conditions which existed, there were many occasions for criticism certain of which might appear to be warranted from the standpoint of the individual. The House of Delegates should know that letters had been received at the Association's headquarters in which the writer complained of the conditions of service in which he found himself, or criticised the Association's war policy. For instance, physicians called to active service and then held in training camps complained because they were not assigned to posts in connection with armed forces. On the other hand, physicians in service overseas duty argued that because they had been kept away from home for a considerable period of time, they should be given the preference of being returned to civil practice. Manifestly these matters were not within the province of the Association. In connection with the complaints because of delayed discharges, it must be remembered that a sufficient personnel of the Medical Corps must be retained in the service until the army has been reduced to a peace status. Reports regarding the return of physicians to civil practice received from the different State associations were gratifying; it was almost the universal comment that these physicians were finding a hearty reception in the localities where they formerly practiced. When these physicians located in new communities, they were in practically all instances welcomed by the medical profession of the locality. The State associations and the county medical societies undoubtedly would find a field for effective service in assisting these returning physicians to reestablish themselves in civilian practice. It could not be expected that an exact pre-war status would ever be restored. The task which confronted the American Medical Association, with its constituent State associations and component county societies, was to assist in bringing about a better state of affairs in the medical profession. Attention was called to the fact that the several military services had commissioned physicians without regard to the fact that a considerable number of them had graduated from socalled sectarian schools. All commissioned medical officers served under similar conditions and used in their professional work the same standard of equipment. Sectarianism found no place in the medical military service. In this respect the war experience had confirmed the position which the American Medical Association had maintained for so long. The Association might have a proper pride in emphasizing that it was a nonsectarian, all inclusive, organization of physicians. This report contained recommendations to the effect that the by-law reading that "Not more than three Honorary Fellows shall be elected in any one year" be amended to read, "Not more than three Honorary Fellows shall be elected at any annual session; provided, however, that on recommendation of the Council on Scientific Assembly, and by unanimous vote the House may elect more than three Honorary Fellows." This was because the present meeting being a Victory Meeting, the Association should be in a position to elect more than three honorary members. It was also suggested that Fellows of the Scientific Assembly of the Association be permitted to use an authorized designation after their names in signing scientific papers or under other conditions where it was desirable to indicate their Fellowship. The following designations had been proposed: F. S. A.—Fellow Scientific Assembly; F. A. M. A.—Fellow American Medical Association; F. S. A. A. M. A.—Fellow Scientific Assembly of the American Medical Association. It would seem advisable that the symbol, if one were adopted, should recognize that Fellowship was a relationship to the Scientific Assembly.

Report of the Board of Trustees.—Dr. FRANK BILLINGS of Chicago presented this report, which showed that rather pessimistic outlook as regarded the *Journal* that was taken two years ago at the outbreak of the war, had not been justified by subsequent events, as was shown by the tables giving the circulation of the *Journal*. The increase in subscription for the year 1918 was small—229 all told—but this under the circumstances must be regarded as satisfactory. The weekly circulation during the first four months of the current year was greater than that in any previous four months, averaging over 70,000. The foreign circulation was also steadily increasing. The advertising standard of the *Journal* had been maintained, or, if anything, censorship had been more rigid. The wisdom of establishing the Cooperative Medical Advertising Bureau became more evident each year. This bureau had demonstrated that it was possible to secure for the State journals a fair amount of advertising of which the profession need not be ashamed. The bureau began this year with twenty-six State journals; the only State journal not represented was that of Illinois. The *Archives of Internal Medicine* had been conducted at a loss, while the *American Journal of Diseaes of Children* showed a small profit. The Spanish edition of the *Journal* was now issued on the first and fifteenth of each month and contained practically all the scientific material in the regular edition but matter that was ephemeral or of local interest was not included. The subscriptions were coming in rapidly and at present it had a circulation of 1,400. In response to a petition signed by a large number of leadnig neurologists and psychiatrists the *Archives of Neurology and Psychiatry* had been established. It was published on the same terms as the *Archives of Internal Medicine*. This journal might already be regarded as a success. It was of the highest order, a credit to American medicine, and to the Association. It was to be emphasized that the Association was not publishing these journals for financial gain; its sole object was to advance scientific medicine and to benefit the American medical profession. The Board of Trustees was of the opinion that the Association should publish more of these special journals if, and when, there was a call for them. Both the American Medical Directory and the Quarterly Cumulative Medical Index showed the effects of the war and had been published at a considerable loss.

Council on Pharmacy and Chemistry.—This report showed that during the past year the Council on Pharmacy and Chemistry had been less active than usual, many of its members being in Government service. However, this Council had been active in war work. Early in the year Colonel Darnell, chief of the purchasing division of the Surgeon-General's Office, asked for the cooperation of the Council in revising the field and post lists of drugs, with a view to their modification. In response to this request the Therapeutic Committee (composed of Dr. R. A. Hatcher of Cornell, Dr. John Howland of Johns Hopkins, Dr. Reid Hunt of Harvard, Dr. Torald Sollmann of Western Reserve, and Professor Puckner) met in Chicago in April, 1918. Dr. W. E. Post of Chicago and Col. Henry I. Raymond, chief surgeon of the Central Department of the Army, also were present—the latter because of his familiarity with the needs of the army under various circumstances. The committee devoted two full days to the work and later presented a formal report, in which specific recommendations, including additions, deletions and modifications, were made. The report of the committee was adopted in practically every detail. This work was far more important than this simple paragraph indicates. Another service which is worthy of specific mention is the cooperation of the Council and the Chemical Laboratory with the Surgeon General's Office in investigating and passing on the many medicinal products offered to the Surgeon General for use in treating the sick soldier both in the hospital and in the field. To one not having personal knowledge of the facts it would seem unbelievable that such a variety of fakes would be offered in earnest to the Government under such conditions. One phase was interesting, and yet pathetic: no matter how fraudulent, how fakish, or how ridiculous the wares might be, their promoters were able to get political influence, even certain Senators and Congressmen, to help them. Automatically, all medicinal preparations offered the Surgeon General were referred to the Council. This Council had been taking up some rather important problems, such as synthetic drugs, nonspecific protein therapy, serums, and vaccines. There had never been a time when there was greater need for scientific research and investigation in the field of therapeutics than the present. Much energy was being expended in this and other countries in the development of industries that heretofore had been monopolized by Germany. This applied especially to the development of the dye industry and its by-products—the source from which had come a few good but many worthless therapeutic agents. We might expect a flood of synthetics equal to, if not greater than, the supply that came from Germany before the war. Unless we were careful there would be a repetition of the past in this regard where the medical men were exploited in trying out new synthetics. A safe guide for physicians who desired to protect themselves and their patients would be the reports of the Council on Pharmacy and Chemistry. One of the publications of the American Chemical Society was urging cooperative research on the part of the society in this development, their object being to encourage chemical industry; but the society could do no better or more patriotic service than to provide means for clinical investigation of any new product offered. Everything was being done to develop these industries, but it would be left to the medical profession to guard against worthless synthetics. This the Council on Pharmacy and Chemistry would do, and do successfully, if supported by the profession.

Propaganda Department.—The war had affected the Propaganda Department. At the same time it gave this department, as the others, an opportunity to cooperate with and be of service to the Government in its work An offer was made to donate a complete set of the publications on the nostrum evil and quackery to the libraries of all camps and cantonments. The offer met with immediate response, and sets of "Nostrums and Quackery," "The Great American Fraud," and the complete set of propaganda pamphlets covering the same subjects were sent to the various camps. In connection with the national problem of combating venereal disease the society had printed for the Army Medical Department 30,000 copies of the "Manual of Treatment of Venereal Diseases." When the Public Health Service took up this work it asked for 70,000 copies of the "Manual." Later orders came from some of the State boards of health. Practically 100,000 copies of the "Manual" had been printed for the Public Health Service and the State boards of health.

Disposition of Lawsuits.—Last year the report of the Board of Trustees presented a statement regarding the disposition of five lawsuits during the year 1917, each claiming damages of $100,000, and in addition the Lydston suit attacking the constitutional rights of the Association to meet and transact business outside the State of Illinois. During 1918 three more suits had been disposed of. The Jenner Medical College *vs.* the Association and the Council on Medical Education, for half a million dollars. This case, which had been pending, was dismissed on March 6. Two cases of E. Wells Kellogg and Edward Patrick Cooke, each for $100,000 for libel, based on an article published in the *Journal*, exposing the Friedmann consumption cure, with which their names were connected, were dismissed in April.

Buildings.—The Association's increased activities were beginning to crowd the haedquarters, especially in the printing department. The board had under consideration the proposition of tearing down the old building and extending the main building to take in this space. If this were done they should have a steel and concrete structure, 100 x 120 feet, six stories and basement. The present valuation of the buildings was $231,463.59. As the War Committee would make a report on the activities of the Association in connection with war that subject would not be touched upon, and likewise a report would be presented on the Investigation and Standardization of Hospitals, but it seemed worth while mentioning that this work had been begun in 1906 and had been developing since that time, and an abundance of accurate data had been collected in regard to the number and character of hospitals, their bed capacity, and the physicians on the attending staffs. The efforts toward standardizing the hospitals, especially those providing internships for medical graduates, was being energetically pressed, and in this movement the abundance of data collected would be of service.

The Treasurer's Report.—The Board of Trustees presented this as an addenda to their report. The auditor's accounts submitted in detail showed that the surplus at the beginning of the year amounted to $423,433.87 and the surplus at the end of the year amounted to $471,-661.50, an increase of $48,227.63. The assets of the Association on December 31, 1918, were estimated at $302,758.84 and reserve fund investment at $208,727.38.

Report of Judicial Council.—Dr. M. L. HARRIS of Chicago presented this report, which first considered an amendment to the constitution introduced last year by Dr. W. T. Wooton of Arkansas and which had been referred to the Judicial Council. These resolutions were as follows:

"*Resolved*, That the President of the American Medical Association, the Chairman of the House of Delegates, with the chairmen of the various sections, be and they are hereby appointed a standing committee to select a Council on Standardizing Surgical Procedures and Medical Practice, the number and personnel to be entirely at the committee's discretion, power being hereby given them to fill vacancies or enlarge said Council as necessity may demand; and further appoint an Advisory Committee to said Council should they desire. Be it further

"*Resolved*, That no action of this Council shall be deemed binding on any physician or surgeon, that no effort shall be made to foster any creed, sect, dogma, or other stigma; the object being strictly to weed out fallacies, gather data, and give the profession an unbiased report as to efficacy of procedures in order that we, the rank and file, may not linger in doubt as to what may be considered judicious, conservative practice."

At its meeting held in Chicago, February 5, the Judicial Council carefully considered these resolutions and recommended that the House of Delegates should not constitute the Council suggested. The Judicial Council was of the opinion that the constitution of the Association should more exactly define "membership" and "Fellowship." In order to bring this subject before the house a proposed revision of the constitution was presented which simplified the wording but made no change in sense.

Age and Disability Insurance.—Acting under its

authority to "investigate general professional conditions and all matters pertaining to the relations of physicians to one another and to the public, and to make such recommendations as the House of Delegates and the constituent associations deemed necessary," the Judicial Council was assembling data relating to age and disability insurance for physicians. The secretary of each of the constituent State associations had been asked what, if anything, was being done by that State association or by its component societies, or any of these, with the object of assisting aged and physically incapacitated physicians. Replies had been received from the secretaries of thirty-one of the constituent associations. Many of these responses indicated an interest in the general question, that was in the development of a plan for providing financial assistance for needy aged or physically incapacitated physicians or dependents of physicians. However, with only a few exceptions, no organized, sustained activities having this purpose in view were being conducted by the organization. The Judicial Council had been informed that actuarial statistics bore out the following statement, namely: That on the average of 100 individuals entering on a business career at the age of 25, when these have reached the age of 65 years, five of the 100 would be in comfortable circumstances, financially; six would be self-supporting; fifty-three would be receiving financial assistance of some form; the balance would be dead. It should be recognized that these figures were not limited to professional men, but included those from all walks of life. Nevertheless in the opinion of the Council, they warranted a further investigation and study of the advisability of undertaking some organized effort for the relief of members of the medical profession who were in financial distress because of age or other physical disability.

Report of Council on Health and Public Instruction.—Dr. Victor C. Vaughan of Ann Arbor, Mich., submitted this report, which stated that the break in the work of the Council for nearly two years, owing to diminished appropriations on account of war conditions, the absence of the Secretary and of most of the members of the Council in active service and the almost complete diversion of public interest to war topics, offered a favorable opportunity not only for summarizing and estimating the activities of the Council during the nine years of its existence, but also for the formulation of plans for the future.

He then reviewed briefly the work of the Council since its organization in St. Louis in 1910. In 1914 the Council had directed three general lines of action. These were:

(1) A thorough investigation of present public health conditions in the United States with the view to securing more accurate information on all phases of the public health problem than is now available.

(2) Education of the public by every possible means in order that the people may understand the enormous advances in scientific medical knowledge during the last generation and the possibilities of utilizing such knowledge in the prevention of disease, the reduction of the death rate and the prolongation of human life.

(3) The crystallizing of such educated sentiment in necessary public health laws which will render possible the conservation of human life commensurate with our advancing knowledge and will render such laws effective through the only force available in this country, namely, educated and enlightened public opinion. Under the first head, namely, the investigation of the present public health situation, need for additional knowledge was subdivided into four classes, namely, (*a*) public health activities of the federal government; (*b*) state public health activities; (*c*) municipal health organization; (*d*) voluntary public health organization. It became necessary therefore in planning for the reconstruction of the activities of the Council to reconsider the plans previously proposed and endorsed by the House of Delegates and to discuss them in the light of actual accomplishment. Regarding the general plan of public education carried on for a number of years through press bulletins, the speakers' bureau, public meetings, distribution of pamphlets, leaflets, etc.,—these methods, while largely new at the time they were inaugurated, had been taken up by other organizations. It had been the policy of the Council not to undertake work that was being done by other organizations nor to attempt to compete with other organizations carrying on public health work, the desire of the Council being to inaugurate work that could not well be undertaken by other bodies and to coordinate existing organizations by drawing them together for a common purpose rather than to create or perpetuate any rivalry between existing organizations. It seemed evident that the propaganda period in public health work was past. Many of our national health organizations, either special or general, as well as many of our state boards of health were now sending out press bulletins and much suitable health material was now being supplied to newspapers. It was, therefore, doubtful whether anything would be gained by the reestablishment of the Press Bureau. In fact, it seemed highly probable that the continuation of this work could be safely left to special organizations. The same thing was true regarding the Speakers' Bureau. A large number of organizations, either local, state or national, had followed the lead of the American Medical Association in this particular in the last five years. It was especially doubtful whether with the limited resources of the Council it would be advisable to attempt the financing of speakers' expenses. As frequent requests for accredited speakers on public health topics continue to come to the Association headquarters, however, it would be advisable to prepare and maintain a list of representative physicians, members of the Association and recognized authorities on some phase of public health work who were willing to give public addresses on various occasions. The increasing number of organizations interested in public health work accentuated the fact brought out by Professor George E. Vincent of the Rockefeller Institute in his address before the American Public Health Association in December, 1918, that one of the most important needs in the public health field to-day was that of increased knowledge of public health conditions. Our knowledge even on fundamental health questions was fragmentary and in many cases based on insufficient foundation. Public health leaders were coming to recognize that improved conditions in the public health field could not be brought about wholly by legislative enactment, and that health conditions could be controlled and improved through public sentiment rather than through restrictive legislation. Especially was it of the utmost importance that the American Medical Association, as the recognized official body of the American medical profession, should have clearly defined objects and purposes, and should know definitely and accurately just what it was trying to accomplish and along what lines its energies were to be exerted. Of the four general subdivisions found in the program as outlined in 1914, none of them had as yet been carefully and exhaustively studied. The subject of voluntary public health organizations was practically in the same condition as five years ago in spite of constant effort to secure better coordination and cooperation. The American Public Health Association had recently taken up the question and had organized a Council composed of a representative number of the fifty-seven different national public health organizations in existence with a view to securing some kind of harmony and cooperation in this field. The creation of unnecessary organizations could not well go much further. The probable outcome would be the absorption of a large number of organizations by some single comprehensive body in the next few years. Whether this would come about by the occupation of the field by the American National Red Cross following its reorganization after the war or by the organization of some new general public health organization along popular lines remained to be seen. It was extremely doubtful whether the Council or the American Medical Association could at present do very much to clarify this situation. It was also doubtful whether the purely educational activities of the Council could at present be enlarged to any extent with any degree of success. There remained, therefore, one field in which the Council and the Association were preeminently fitted to exert themselves, namely, the increase of knowledge regarding organized public health activities. In its report for 1914, the Council said, regarding the need of a careful study of the public health work of the federal government with a view to determining exactly what the federal government was doing and could do for public health: "The need for

such an investigation hardly needed more than to be stated. The American Medical Association stood unreservedly pledged to the securing at the earliest possible moment of an adequate national health organization. This country would never have a federal department of public health such as has been advocated rather vaguely for fifty years past and such as was now being strongly advocated in England, Canada, Australia and other nations until the public health functions and powers of the federal government under the constitution have been definitely determined. Two questions must be answered: First, what could the federal government do for public health; and, second, what was the federal government now doing for public health. These questions were not at present being considered by any other organization, yet their solution was fundamental to the development of public health in this country. They were problems to which the American Medical Association could fittingly and properly direct its attention. Having secured some authoritative information on these two questions, they would then be able to put the influence of the American Medical Association behind an intelligent movement for a national health organization. Regarding the second field for investigation, that of state health activities, the report of the Council in 1914 said, "There is to-day in every state in the Union some form of public health organization. Owing to our form of government, each of these organizations is working independently. As the reports of the various state boards are not made on a uniform basis, a comparison of their various activities and a tabulation of the results secured by their efforts are difficult. It is, therefore, practically impossible to-day to summarize the public health work which is being done by the different state boards of health, to compare one with another or to establish any standards by which their relative merits may be determined. The first necessity for such a comparative study is clearly a collection of authoritative official data on the subject." The report published by Dr. Chapin two years later was the only effort that had been made to obtain a comprehensive view of this field. The large number of requests that had been received for the limited edition of this report showed the value of such a study. In the third field of health activity, namely, municipal health organization, a still greater need for careful study existed. While there were only forty-eight states, each differing as to size, population, physical characteristics, material resources, industrial conditions and public health needs, there are 325 cities of over 25,000 with all possible varieties of health organization. Yet there was no basis of comparison by which it could be determined what form of health organization is best adapted for a city of 25,000, 50,000 or 100,000; how the health organization and the administration in one city compares with another; what the legitimate expense of proper health administration in a city of a certain size should be; what the functions properly undertaken by a city health department should be or how these should be related to a state health organization; or whether or not the people of any city were receiving an adequate return for the amount of money paid out for health purposes. For the city that desired to improve its health organization or to establish one *de novo*, there was no information as to what kind of health organization such a city should have; what should be its personnel or equipment; how much money should be appropriated; or what duties or activities should be imposed on it. An effort had been made by the American Public Health Association in the last few years to discuss this question and to formulate some general principles. No comprehensive study of the question, however, had as yet been made. The plans of the Council provided for a comparative study of the health organization and activities of our various cities in the hope of being able to establish standards for such work for groups of cities of different sizes, to compare the public health work done in our leading cities and by such standardization and comparison to stimulate and encourage better health organization in our American municipalities. Another task taken up by the Council was a study of the legal relations and responsibilities of physicians and the legal aspects of public health. This field, for obvious reasons, had never been carefully studied either by physicians or lawyers. It offered no prospect of financial reward to lawyers and it was only of interest to physicians so far as their personal interests were involved in some specific case.

After commenting on the unjust increase of taxation on the physician under the Harrison law, the Council recommended that the House of Delegates record its emphatic disapproval of this unjustifiable attempt to exploit physicians and that it demand the reduction of the registration fee for physicians to a nominal amount.

Vital Statistics Legislation.—Probably the most successful, in fact the only successful, effort that the American Medical Association had made in late years to influence legislation was now happily nearing completion. It seemed evident that the passage of a model standard law on this subject by each state was absolutely fundamental to public health progress. Accordingly this matter was taken up by the Committee on Medical Legislation, one of the forerunners of the present Council. The newly adopted Pennsylvania law which had been very carefully drafted was taken as a model. A joint committee was organized through cooperation with the American Public Health Association and a model bill was drafted, this being one of the few subjects on which it was possible to draft a standard bill suitable for adoption by every State. Year by year one State after another had fallen into line until at present there were only five States possessing unsatisfactory laws, and only two in which no legislation existed.

Social Insurance.—The introduction during two sessions of the Michigan legislature of bills providing for health insurance and the appointment of commissions to study this subject in a number of States, notably California, Illinois, New Jersey, New York, Ohio, Pennsylvania and Wisconsin, and the introduction of a bill in the New York legislature, all combined to make this question one of the vital issues now before the medical profession. No State had as yet adopted social insurance. In New York the bill endorsed by Governor Smith passed the senate but failed to pass the house. In California, the bill recommended by the State commission was on referendum defeated by a large popular vote. In Wisconsin, the commission reported against the proposition. In Ohio, the commission was in favor of limited social insurance. In Pennsylvania and Illinois, the commission recommended a continuation of its activities and further study of the question. The growing interest shown in this subject during the last two years, however, made it all the more important that careful attention should be given to it by physicians, both as individuals and as a profession. The attitude of the majority of physicians up to date had been one of unqualified and often unreasonig opposition, without any effort to study the question or to consider the arguments put forward in favor of the proposed plan. Unreasoning opposition or sweeping and often erroneous general arguments against the measure would not prevent its adoption nor would it enhance the influence of physicians. It was of the utmost importance to the medical profession at present that we give this question the most careful, painstaking, patient and disinterested study, that we qualify ourselves as authorities instead of allowing this function to be exercised by the active proponents of social insurance. To this end it was particularly necessary that we study this question dispassionataely and critically, discriminating between fundamental principles and nonessential details. There was in this country a certain amount of illness among those whose gross annual incomes were below an amount that would permit them to bear the expense of such disabling and incapacitating illness without being seriously and perhaps permanently handicapped or crippled thereby. Such crippling and disabling illness being conceded, if the individual was not able to carry it alone, then the burden must be lightened in some way. This could be done by increasing the income of the individual, and thus elevating his economic status to a point where he could carry his own burden; by reducing the amount of sickess through the enlarging and improving of State public health activities; or by distributing the cost of existing disabling illness among the three parties at present responsible, namely, the Individual,

the industry, and the State, so as to relieve the individual of from 60 to 80 per cent. of his burden. A fourth possible procedure was simply to leave matters alone as they were. The first of these proposed plans might be called the economic remedy, the second, the state public health remedy; the third was social insurance, and the fourth was no remedy at all. In this discussion many questions arose which could not be answered with our present knowledge. What was the average amount of illness incurred by the average wage earner in the course of the year? How much of a burden was this to him and his family? What was the average amount which the individual lost each year through illness? How much of this loss was due to preventable disease which could be eliminated by increased State health activities and by the better organization of health agencies? What was the minimum annual income that would enable the individual to carry successfully the burden of his own disability? How many American families had an income below this minimum? If the first remedy proposed, that of increasing the annual income to a point where each individual could carry his own burdens, seemed best, how was this desired object to be accomplished? If the second remedy was adopted, namely, increase of governmental health activities to a point where preventable disease was reduced to a minimum, how large a burden of nonpreventable disease would remain? Would not the increase of governmental health activities to such a point produce just as marked and radical a change in the medical profession as the proposed health insurance? What effect would the plan proposed have on the work and income of physicians? Without providing for the unemployed and the indigent, who would still, as in England, have to be cared for under poor laws and charity organizations, would not the increased professional income from case of the insured, whom the doctor today takes care of for little or nothing, increase the average professional income, provided the compensation for professional services could be properly determined? Would not this increase amount to more than the loss due to lowered rates? If the proposed social insurance could be shown to be necessary and to be the best solution of the problem involved, could the medical profession as a class successfully oppose it simply on the ground that it might interfere with or disturb our professional income and livelihood? These were a few of the questions which must be answered satisfactorily in the discussion of this problem. They could be answered only by physicians who had made an effort to acquire some knowledge of the subject and to discuss it impartially rather than from the standpoint of their own prejudices. It was, therefore, of the utmost importance that physicians both as individuals and organizations abandon the attitude of unreasoning opposition which had characterized many of our professional discussions on this question and make an honest effort to study the problems involved and to arrive at conclusions which could be justified. For these reasons, the report of the Subcommittee on Social Insurance was this year of the greatest importance and value and was commended to your special attention. By the end of another year the question might and probably would be a vital issue in a number of States. It was highly important that we improve the interval by learning as much on this question as possible.

Report of Subcommittees of the Council on Health and Public Instruction—Committee on Women's and Children's Welfare.—Miss LENNA L. MEANNES submitted this report which stated that through the past year the committee had found its chief activity in cooperating with the state chairman of the General Federation of Women's Clubs and with the work of the Children's Bureau in the Children Year program. Late in the year a questionnaire had been sent to the state chairmen of public health committees asking certain questions with reference to the work of Children's Year program, certain question with reference to birth registration, and questions concerning social education. It was too early to give the *results* of this questionnaire. In connection with the Children's Year program they had strongly urged the establishment of permanent child welfare stations as the most effective plan to follow the measuring and weighing tests. In some states the child welfare officers of the Council of Defense were being made into permanent child welfare committees. It was the intention to issue a form letter to all states urging the formation of these committees, hoping that this would lead to securing child hygiene departments in state boards of health.

Report of Council on Medical Education.—Dr. JOHN A. DODSON of Chicago submitted this report, which gave a concise résumé of the work done during the fifteen years it had been in existence, along the lines of collecting information, annual conferences, the raising of educational standards, and the raising of the requirements of preliminary education. An outline was then given of the Council's work in the war. The facts to be emphasized were briefly as follows:

Of the 20,678 students who graduated during the last six years, 15,025, or 72.6 per cent., were admitted under the higher entrance requirements, received their training in and graduated from the Class A medical schools, in which the great improvements in recent years had been most pronounced. It was the graduates of these recent years who in the largest proportions entered the Government medical services. As a result, the American soldiers and sailors were attended by a larger proportion of medical officers who had had a modern medical training than they would have obtained had it not been for the Council's campaign for an improved medical education. At the headquarters of the American Medical Association, in the Council's files, the Students' Register and the Biographical Index, there was information regarding medical students and graduates which was not available elsewhere. This information was placed at the service of the surgeon-general, and as a part of the routine in the commissioning of medical officers, lists of applicants were sent to the Association for verification of their graduation and license. In 1917, through the possession of the Students' Register, unanswerable arguments were advanced favoring the exemption of medical students from the draft and as a result the Medical Enlisted Reserve Corps was established.

Graduate Medical Instruction.—The world war had emphasized the great need of better facilities for graduate medical instruction in the United States. Such facilities were in great demand by medical officers as they were being released from active duty since that presented an excellent opportunity for them to take up certain courses of graduate study before returning to active practice. Improved facilities for graduate work were also important to meet the demands of our neighbors in the Spanish countries of Central and South America. The development of graduate work was an important subject to consider in connection with the efforts to standardize hospitals.

After speaking of the various medical cults and emphasizing the point that the chief objection to them was the lack of education of their devotees, the report stated that the work of the Council in connection with low-grade medical colleges, drugless cult institutions and diploma mills had called attention to the lack of adequate safeguards over the chartering of educational institutions in the various States. In all but a few States any group of individuals for a small fee could secure a charter to open an educational institution and to grant all the degrees in the category, no questions being asked in regard to ability, financially or educationally, to furnish the education usually required for such degrees. Attention to the need of such safeguards was called by the secretary in his report to the Council in 1916. Reprints of this report were sent to the educational authorities in each State, and a growing interest is being manifested toward the securing of laws needed to establish such safeguards.

Hospital Standardization.—This part of the report reviewed the work done in hospital standardization during previous years and then told of the third survey made during the past year. In October, 1918, there were in the United States 6,468 hospitals having ten or more beds, or a total capacity of 758,442 beds. The distribution of these by States was shown in Table 1. Of these hospitals 4,927 had from 10 to 100 beds; 817 had from 100 to 200; 447 had from 200 to 500, and 277 had over 500 beds. Blanks inquiring data in regard to

interns sent to all hospitals brought the information that 5,342, or 82.6 per cent., did not use interns, and only 1,126, or 17.4 per cent., were using or desired to have them. These 1,126 hospitals, however, included the larger institutions, and had 35.6 per cent. of the total bed capacity. There were 274 more hospitals desiring interns than were listed in 1913, and 439 more than were listed in 1916. These had a total number of 270,401 beds (including eighty-four hospitals for the insane, with 97,421 beds). At the rate of thirty beds per intern for the general hospitals and a total of 174 interns in the State hospitals, places are provided for 5,940 interns or resident physicians, as compared with 3,566 in 1913 and 4,057 in 1916. This showed the remarkable increase in the appreciation of and demand for interns; it showed also the utter impossibility of graduating a sufficient number of medical students to meet the demand, even if we should multiply by four the number of physicians now graduating annually from our medical schools; it showed the necessity of employing house physicians, or of providing special assistants, who would do much of the work heretofore devolving on the intern. The report also presented a tentative schedule of essentials for the satisfactory training of interns. This insisted upon the necessity of an organized staff of physicians of unquestionable integrity, both professionally and morally, who should be proficient in the special fields in which they worked in the hospital. They should give personal attention to the patients under their charge. They should assume an obligation to direct and supervise the training of the interns admitted to the staff. There should be clinical and pathological conferences and hospital medical societies at which staff members and internes should be encouraged to present cases which had been worked up from the clinical point of view and on which they had read up the available literature. Definite equipment for hospitals had been decided upon and included a fully equipped pathological and clinical laboratories, a roentgen-ray department in charge of an expert, roentgenologist and a working medical library containing a fair supply of standard text and reference books, the better medical journals, and suitable charts and models. Stress was laid on the need for complete histories and records, carefully kept and in charge of a trained historian. The work outlined for the intern included clinical laboratory work, roentgen-ray work, anesthetics, dietetics, maternity, necropsies, and a constantly increasing responsibility, under careful supervision, in the diagnosis, daily observation, care and treatment of the patients under his service. The intern should obtain a practical experience in the applying of surgical dressings in connection with the care and treatment of patients. As he progressed in his surgical intern service he should be authorized under careful supervision to perform not only minor surgical operations, but also some of the more common major operations. In major operations, the attending surgeon should stand by, or assist the intern. Experience in connection with accident service was likewise highly desirable. The intern service should extend through at least twelve months, and might to great advantage be continued through eighteen months or two years. Reports from the eighty-five medical colleges which conducted classes during the session of 1918-1919 showed that the total enrolment of medical students was approximately 12,090, or 1,540 less than for the session of 1917-1918. The reduction was mainly in the freshman classes, of which the total enrolment was approximately 2,810 for the present session, as compared with 4,283 for the previous session. This unusual decrease was due clearly to the volunteering or drafting of premedical students for military service during 1917-1918. With the beginning of another session following the return of soldiers and sailors to civilian life, the enrolments of students in our medical colleges would return to their prewar proportions. The unusual demand for medical officers naturally created a temporary scarcity of physicians for hospitals and civilian needs, but this was to be expected, and was merely a parallel to the scarcity of experts in other lines of human activities—a scarcity which would undoubtedly disappear following the return of medical officers to a civilian status. The world war had called attention to special needs in every line of human endeavor. No previous war had so involved the entire world or so hazarded the very existence of practically every civilized government. In no previous war was such extensive use made of those who had reached the highest attainments of human skill and ingenuity. The urgency and extent of this demand naturally drew attention to the scarcity of those who were qualified to render service along highly technical or specialized lines. So in medicine there was an unprecedented demand for physicians of exceptional qualifications and skill in the various specialties, such as pathologists, bacteriologists, psychiatrists, brain surgeons, oculists, etc. Here, likewise, the urgency of the demand had forcibly revealed the fact that the supply of physicians having such skill is comparatively limited. This revelation, however, was not a criticism of medical education of the past, but laid emphasis on the possibilities and aims of medical education in the future. The war had rendered a great service in revealing the possibilities and benefits that will result from higher attainments in medicine. This showed the necessity of continuing the campaign for improvements not only in udergraduate but also in graduate medical education. If the highest attainments were of such vital importance in great national crises, how much greater would be the service to the public whether there be peace or war. The supply of physicians in this country was still greater in proportion to the population than that of any other civilized country. According to the sixth edition of the American Medical Directory, completed in 1918, the United States had 147,812 physicians. The total population of the United States, as given in an estimate of the Census Bureau in 1918, was 105,253,300—which was one physician for every 712 people. Various reports regarding the proportion of physicians to population in the countries of Europe just prior to the war show that in those countries the proportion ranged from one to 1,500 to one to 2,500. This country, therefore, still had twice as many physicians to population as the most favored country of Europe. One of the great benefits of the world war was that attention had been called to the great importance of a better training of physicians, particularly along the line of the narrowed specialties. A tremendous interest in postgraduate medical education had developed not only in the United States, but also in European and other countries. In all our larger cities there was an abundance of clinical teaching material which would be most useful for graduate medical instruction, but which was widely scattered and not readily accessible to the student. It must first be catalogued and administered by a single organization so that information regarding the work could be obtained by the students by applying at a single place rather than at several widely scattered places. A report had just been received indicating that in New York City a movement was on foot to pool all of the hospital facilities for the development of a great scheme for postgradute medical education, and doubtless similar movements will soon be evident in other large cities. The closer friendship and harmony between the United States and the sister republics of Central and South America—another result of the war—would be further extended if through the development of postgraduate medical education students from South American countries would be induced to and could readily obtain instruction in such subjects as they might desire. In this connection, the exchange of professors between this and European countries and the proposed exchange of clinical clerks and clinical assistants were steps in the right direction. The arrangement should be extended also to the countries of Central and South America. In outlining its plans for the coming year, the report stated that it was the intention of the Council to continue the work it had been doing and to make a reinspection of medical colleges and an insnection of all hospitals undertaking to train internes. This could be done in connection with the inspection of medical schools, and would in no way conflict with the inspection of hospitals in general being made by the American College of Surgeons and other agencies. A continued study of postgraduate medical education in the United States and publicity regarding the needs of further development along that line were included in the plans of the coming year. Continued efforts would be made to safeguard each State over the chartering of educational institutions.

Report of Council on Scientific Assembly.—Dr. E. S. Judd of Rochester, Minn., submitted this report, which outlined the new plan by which at this annual session the sections were divided into groups, the one group to meet in the morning hours and the other group in the afternoon hours. Rules in regard to the presentation of papers and the reading and discussion were formulated. The number of papers on the program of any one section was limited to twenty-five. In compliance with the request of the Section on Genito-Urinary Diseases, the Council recommended that the name of this Section be changed to the Section on Urology.

Report of War Committee of the American Medical Association.—Dr. Hubert Work of Pueblo, Col., submitted this report, which showed that, according to the records of the Association, the applications for commissions in the Medical Corps of the Army were: June, 2,416; July, 2,841; August, 3,814; September, 4,171; October, 3,113, and during November, the month of the Armistice, 632 total, 16,987 commissions from June 1, 1918, to the cessation of hostilities. The American Medical Association had been the center of information concerning medical military matters for physicians. Replies to individual inquiries had involved the activities of several of the departments at the Association headquarters, and letters to individual physicians during the period of hostilities frequently numbered over 100 each week. In addition, since last June, more than 5,000 pamphlets covering information pertaining to entrance into the Medical Corps were distributed in response to individual requests. The expense involved, including printing, postage and other items, has been borne by the Association. The American Medical Association supplied State and county organizations with detailed information concerning the physicians in their own communities who were available for civil and industrial practice, and had cooperated with these branch organizations in enlisting the services of additional physicians where the needs of a locality could not be met by physicians still remaining in civilian practice in these communities. The Committee congratulated the Association, through the House of Delegates, on the nationwide service which the Association had renederd, especially in that its organization was made available for assembling and proving medical data to the executive heads of several Federal departments which required the cooperation and assistance of the medical profession both in caring for the force under arms and in the execution of the Selective Service regulations. The work of the Association along these lines had received the recognition of the Provost Marshal General to the Secretary of War, the Surgeon-Generals of the Army, of the Navy, and of the Public Health Service.

Report of Subcommittee on Social Insurance.—Dr. Alexander Lambert of New York submitted this supplementary report in which he stated that during the years 1915, 1916, and 1917 the committee had inquired extensively into the question of whether there was a sickness problem, what it was, and how it was to be met. The findings were that 2.6 of the population were seriously sick all the time; 1.5 were more or less disabled, that was simply below par, and that among the 38,000,000 employees in the United States there was an average of nine days' illness per man per year. A study of the sick benefit funds revealed the fact that the cases with less than twenty-six weeks' duration of illness in a year represented 90 per cent. of the illness, and the cases that were ill more than 26 weeks in a year represented 10 per cent., and these cases of serious illness bore most of the economic loss. In figures about $500,000,000 a year would represent the loss in wages by the wage earners from sickness. The amount of sickness in a family was found to be inversely as the wages of the family, that was, the poorer the family the higher the sickness rate; also the sickness rate was higher in proportion as the number in the family increased. The sickness rate was 38 per cent. higher among the poor than among the more comfortable classes; naturally the infant mortality rate was higher among these poorer families. In well-to-do families the infant mortality rate averages 41 per thousand births, while among the poorer it averaged 225 per thousand births. It was found that on an average among the poorer families 16 per cent. of the income was spent on medical care, and the kind of care they received was proportionately less efficient, and in a great many cases the patients received no medical care at all. The dispensary statistics showed that 75 per cent. of sick patients had had no previous medical care at all. Only 25 per cent of pregnant women received anything like adequate antenatal care. In Philadelphia, 60 per cent. of the sick poor had only home care and patent medicines were found to be used by from 25 to 50 per cent. of these persons. In about 35 per cent. of the cases the wage earner had sickness insurance amounting to 10 or 15 per cent. of his wages; some carried a voluntary insurance, but the larger proportion had no insurance against sickness. The question was raised, "How should this burden be distributed so that it should relieve those who were unable to bear it?" The medical profession could not go on giving medical service as it had formerly done for medicine had grown so much in all directions that the medical man could not furnish the medical care that he formerly could supply. Large industrial employers had come to realize that sickness was a serious expense and they made the effort to restore the trained worker to his post as soon as possible. The question before them was "Does the remedy lie with sickness insurance?" The whole situation had become economically top-heavy. Both labor and industry realized the necessity for change and therefore it was obviously the duty of the medical profession to meet labor and industry half way. General insurance schemes in Germany and England had not been found to work well. They were designed to lift the strain from the poor, but they had degraded the medical profession to the level of lodge practice. The German insurance scheme was sprung on a medical profession comatose with indifference and it took twenty years in Germany to place it on a better footing. In England the plan of a pro rata per patient per year payment was only extended lodge payment practice which always produced evil results. There was no excuse for the medical profession in America to copy the mistakes made in Germany and England. No detailed plan was presented at this meeting. The solution must be found through the organized aid of the medical profession with the help of the State and county medical societies. The men must wake up to their responsibilities and learn all that was possible on this subject in order to obtain their own protection and that of the public. The medical profession should decide whether better protection against sickness should be obtained through the increase of State health department control, or whether it should be done as in England through a pro rata per man per year fund.

These reports were referred to their appropriate reference committees.

Second Day—Tuesday, June 10.

Dr. Hubert Work of Pueblo, Col., in the Chair.

Reports of Reference Committees.—The Reference Committee on Sections and Section Work, which had under consideration the report of the Council on Scientific Assembly, approved of the plan of dividing the section work into two groups and recommended to the House of Delegates that the plan be continued at the meeting of the Association next year. There were two reasons why this plan seemed advisable. In the first place it provided more time for some form of recreation and for the men to get together in social ways, and in the second place it gave an opportunity for the general practitioner and for men interested in somewhat similar lines of work to get together. For example, it gave an opportunity for the men interested in general medicine to meet with the men interested in diseases of children or other subjects allied to general medicine. The only disadvantage that the plan possessed was that it limited the number of papers that could be presented. In looking over the program it would be seen that an unusually large number of the older men were reading papers, men who read papers year after year, and the question suggested itself whether or not the House of Delegates should take some action to the end that more papers might be presented by the younger men in the profes-

sion. The function of the Association was educational and the younger men should be encouraged to present contributions. While the committee had taken no action on this matter, it might be a wise step if the House of Delegates could regulate the section work in such a way that perhaps a man could not read a paper more than once in two or three years, after he had been in practice for a certain number of years. The recommendation for limiting the number of papers to twenty-five had been referred to the Committee on By-Laws for action. This report was adopted by the House with the recommendation contained therein.

Reference Committee on Medical Education.—This committee stated that it had carefully considered the report of the Council on Medical Education and was greatly impressed by the progress that had been made. The chief factors in the report were the surveys that had been made and the publicity given to the results of these surveys. The committee recommended that the Council should instruct State boards to use this information and that it be used by student bodies. Attention was directed to the table that had been presented showing that the public was not being properly protected against low-grade doctors and which made it evident that there was still much that was not ideal in medical education and licensure at the present time. It was the opinion of the committee that many more hospitals might become teaching institutions. This report was adopted as a whole.

Reference Committee on Legislation and Political Action.—This committee recommended that the report on social insurance be adopted *in toto* and that the committee be thanked for the immense amount of work it had done. This report was adopted. The committee recommended the adoption of the motion that a special narcotic drug committee be appointed to work in conjunction with the Council on Health and Public Instruction. This committee was to meet in conference with the Internal Revenue Officer and representatives of the wholesale and retail dealers in narcotic drugs. This recommendation was adopted.

Report of Committee on Amendments to Constitution and By-Laws.—The committee stated that the Judicial Council had presented changes in the constitution and by-laws which affected almost every section. Ordinarily these amendments must lie over until another year, but they had been referred to the committee in order to get special opinions in reference to these proposed changes. The committee recommended that they lie over until another year that in the meantime a study be made of the changes proposed, and that suggestions be submitted during the year so that at the next meeting they would be prepared for comprehensive action. The committee invited information and suggestions on these proposed changes. This report was adopted.

New Business.—Under this heading a number of resolutions were introduced among which were the following:

A resolution to the effect that the Council on Health and Public Instruction should cooperate with the Council on Medical Education in developing a program of physical education for the children of the nation. It was stated that the National Educational Association had formulated a plan for physical education through the cooperation of the Federal and State governments. Under this plan the Federal Government was to supply the funds and the States the equipment.

Resolutions providing that a report on the status of post-graduate medical education should be presented at the next annual meeting of the Association, showing the results of the investigation that was being undertaken.

Resolutions instructing the Council on Pharmacy and Chemistry to confer with reliable drug and pharmaceutical interests of the country with the idea of getting their cooperation.

A motion providing that the publication of a *Journal of Surgery* be considered and also the publication of a *Journal of Medicine* for lay readers, if the House found such a procedure advisable.

Resolutions commending that part of the report dealing with insurance for physicians in their old age. The Council was to continue its investigations on this subject and to present a plan when it had found a suitable one.

Resolutions from the delegates from New York State opposing compulsory health insurance, in accordance with instructions from the Medical Society of the State of New York.

Resolutions putting the medical profession of the country on record as opposed to the bill at Washington to forbid the use of dogs for experimental purposes by surgeons, inasmuch as such a law would seriously interfere with scientific research.

Resolutions recommending midwinter conferences between secretaries of the State medical societies and officers of the national body for the dissemination of the latest approved practices in medicine.

The above resolutions and motions were carried.

The House of Delegates, by a rising vote, adopted a resolution in memory of the members of the profession who made the supreme sacrifice for civilization's sake.

Resolutions opposing the repeal of the daylight saving law were referred to a committee for consideration.

A motion providing for an open forum at each year's meeting of the American Medical Association for the free and frank discussion of noncensored topics met with summary defeat. Resolutions were passed, however, whereby the House of Delegates was privileged at option to go into the committee of the whole to discuss any subject delegates might care to present.

A motion was carried to the effect that there should be a saving for the use of army and navy surgeons of the valuable works on medicine and surgery from the Surgeon General's office, which under existing conditions were likely to be destroyed. Recommendations were made instructing the Board of Trustees to take steps to accomplish this purpose.

OPENING MEETING.

Tuesday, June 19, 1919.

THE PRESIDENT, DR. ARTHUR DEAN BEVAN, OF CHICAGO, IN THE CHAIR.

THE meeting was called to order by the President.

Invocation.—The Rev. Dr. ABNER H. LUCAS of Atlantic City made this invocation.

Address of Welcome from Atlantic City.—HON. HARRY BACHARACH, Mayor of Atlantic City, made this address in which he said, in part, that his being here to address the American Medical Association on behalf of the great Convention City was a mere matter of form, for, as everyone knew, the American Medical Association was welcome not only in Atlantic City, but in every city in this great country of ours. Men and women who had so loyally performed the work of their profession, not only in this country, but who had been willing to make the sacrifices and risks of service in other lands in order that human life might be saved, need not be told that they were welcome. So as he had said it was a mere matter of form to welcome them, but it was more than that, it was a privilege, a pleasure, and an honor to welcome those who represented so much in American history. They appreciated the honor of having this Association in their great city, where they had no munition factories or great industries and where their chief business was to offer the opportunities for recreation. He was not only proud of the city for the advantages it offered because of its safety, cleanliness, and hospitality, but because in all the drives for loans of a patriotic nature Atlantic City had gone over the top. They had had 3,500 boys in the country's service. When the war broke out they had organized a Liberty Club to take care of the families of the boys who had answered the call of our country, and not only to take care of them, but to take care of them in such a manner as the families of the soldiers and sailors of this country should be cared for. In Atlantic City they wanted nothing but 100 per cent. Americans. The Bolsheviki and those of that type who were not willing to fight for Old Glory should go back to the countries from whence they came. This war had served to impress upon each one of us one thing, that there was no North, no South, no East, and no West. In closing he said he hoped the stay of the members of the American Medical Association in Atlantic City would be pleasant as well as profitable and that it would prove favorable not only in a professional way to this country, but to the world at large. He

presented the Association, he said, not only with the key to Atlantic City, but with the key to the hearts of Atlantic City. He then presented the president of the Association with a large silver key.

Address of Welcome from the Medical Society of New Jersey.—Dr. THOMAS HARVEY of Orange, N. J., president of the Medical Society of the State of New Jersey, made this address of welcome in behalf of the medical profession of the State. He said, in part, that it was his duty to extend a welcome to the members of the American Medical Association on behalf of the profession of this very compact little State from the dells of Sussex to the shining sands of Cape May. It was fitting that their society should join in this welcome. Their society being 100 years old had at least a grandmother's interest in the youthful association which had just reached its seventieth birthday. This was the time of all that we should meet here, now that we had reached the piping times of peace and were again free from the horrors of war that had hung over us for the past two years. It was fitting to recall that there were men among our number who had laid their all on the altar of their country and it was also fitting to remember that other army at home that had spent so much time and labor in selecting the men suitable for the service. It was also fitting that we should remember and welcome the medical men of the allies who had borne the heat of the day so far as the war was concerned and who had met the problems of war with such wonderful skill that when we finally came into the war we found the problems of war surgery so worked out that we had only to apply the details. They welcomed those who had gone into the trenches and offered up the supreme sacrifice and whose spirits were here at this victory meeting watching to see if we were faithful to our trust in carrying succor to those afflicted with disease. We should take great pride in the work of the doctors in the war. They had greatly reduced the number of permanent casualties. In this work the medical profession of New Jersey had done its part, about one-third of them going into the service. If doctors were to keep medicine as one of the liberal professions they must antagonize all efforts to reduce the medical profession to the level of a trade; but if the practice of medicine was to be a trade the medical men must organize and employ union methods for their protection. In closing Dr. Harvey said that if after having devoted themselves to enlarging their views on medical subjects in Atlantic City for a week, they wished to drink deeper of the fountain of Æsculapius he hoped they would come to the meeting of the Medical Society of the State of New Jersey at Spring Lake a little later.

Address of the President-Elect.—Dr. ALEXANDER LAMBERT of New York delivered this address. (See page 983.

Introduction of Foreign Guests.—Among these were: Dr. Ernest W. Hey Grove, England; Sir St. Clair Thomson, England; Major General Sir Bertrand Dawson, England; Lt.-Col. Shirley Murphy, England; Sir William Arbuthnot Lane, England; Sir Arthur Newsholme, England; Mrs. Eleanor Barton, England; Col. W. T. Lister, England; General Melis, Belgium; Col. A. Depage, Belgium; Dr. P. Nolf, Belgium; Prof. J. Duesberg, Belgium; Capt. Van Der Velde, Belgium; Capt. René Sand, Belgium; Dr. Maurice Heitz-Boyer, France; Dr. C. Mullon, France; Dr. Pedro Chutro, Buenos Aires; Dr. Juan Guiteras, Cuba; Dr. Emilio Martinez, Cuba; Dr. Francisco M. Fernandez, Cuba; Dr. Israel Holmgren, Sweden; Dr. Sven Ingvar, Sweden; Dr. Peter F. Holst, Norway; Dr. John Constas, Greece; Dr. Caroussos, Greece; Dr. Asajiro Kamimura, Japan; Dr. Ryuzo Kodama, Japan.

Wednesday Evening, June 11, 1919.

THE PRESIDENT, DR. ALEXANDER LAMBERT OF NEW YORK, IN THE CHAIR.

AT this meeting national organizations, the activities of each of which have a definite medical interest, were represented by speakers of their choice. Each speaker gave a ten-minute address on the general subject of American medicine and surgery as it responded in service under war conditions.

ASSISTANT SURGEON GENERAL WINTER, representing Surgeon General Ireland, made the opening address. After paying a high tribute to Surgeon General Ireland and apologizing for himself as a substitute, he said it was with no sense of apology that he made a few observations in regard to the medical department of the army, both at home and abroad. A large number of capable men had given up lucrative practices to serve with the army, and these men in the Medical Reserve Corps had formed a large and important group. Many things that were lacking in this branch of the service early in the war had now been supplied. It had been the duty of the regular medical officers to advise and cooperate with the Medical Reserve Corps. There had been considerable criticism as to the things done and the things left undone but before being too severe we must consider the human agencies involved and the difficulties that were presented. It was easy to give credit to the men who had entered the Medical Reserve Corps and had identified themselves with the war, but to his mind the doctors representing America abroad and those doing the work of medicine and surgery at home were equally deserving of credit. It took the war to get the full measure of men, and he had constantly been impressed with the absolute and complete consecration of the medical men to the every-day task. His identification with these men had been a matter of satisfaction and congratulation. The medical department of the army had functioned to a satisfactory finish. It was not always done *lege artis*. They had fallen short of the ideal, but they had given what they had to the work and they had gotten the best results possible under the conditions that obtained. One could not, under war conditions, expect the perfection that we had in quiet times, but certainly the hospitalization and attendance our soldiers and sailors received was such as had never been given in any previous war, and they had striven for better than they had been able to attain. As to who deserved the credit, he believed it was due to the whole Medical Corps, backed up by the American Medical Association, and there was no particular distinction to be made between the men who were in the Regular Army and those who had left their work and entered the Medical Reserve Corps. The matter of rendering assistance to the American soldier was the mainspring impelling them both, and no endeavor was too great when that ideal was seen before them. There were some sore places with some people. That lay in the fact that promotions did not come in the way that it was thought they should come. There were reasons for this beyond the control of the medical department. There never was a time when the chief medical authorities were not thoroughly and actively alive in their efforts to secure recognition for deserving medical men. As to who carried on the work of the medical department, there were at the outbreak of the war 447 medical men who had had military training of two years or over. These had to be distributed among 34,000 medical officers, and it was needless to speak of the insufficiency of that leaven. They had their faults and their misfits but the seniors among them strove to correct and ameliorate conditions created by these. Errors were made because they were confronted with new things, but he felt that they had made no greater mistakes than were made by England and France in the early days of 1914 and 1915. They had learned many things in France along many lines. Personally, he felt that his best heritage from the war was the consolidation of his affection with his fellow doctors. To have known them and to have seen their splendid manifestation of courage and self-sacrifice was a privilege and a delight and a *vade mecum* to any man who had reached the shady side of fifty years. The vast majority of men in the medical department had served well. The millennium would have arrived had not a few mistakes been made and a few criticisms come up.

Dr. JAMES R. PHELPS, Commandant, U. S. N., made a brief address as the representative of Surgeon General Braisted. He said that the death rate for the first year of the war in the United States Navy was lower than for the previous year of peace. The death rate in the navy for the period of the war reflected the greatest credit upon the profession, the Medical Corps of the navy, and the Surgeon General for his able leadership. The rate was 8.8, the lowest ever reached by the naval

or military service at war. The war was over and now they were having the invariable aftermath, when it was customary to indulge in fault finding and when faults assumed the proportion of criminal negligences. It was equally as impossible to do justice to the energy, intelligence, and devotion displayed by the members of this Association, as it was to give due commendation to the men in every branch of this department. Had any one prophesied in 1912 that within five years this country would have defied tradition and sent two million men to fight in Europe it would have been said that that man was out of his mind. Yet this had come to pass. Ought we not now demand that some widespread effort be made which would save more lives, in case of another war, than were saved in this war. We must urge the upkeep for health, for upon it depended the worth of men in a time of emergency. The first step in preparedness for future wars was to promote a standard of physical efficiency in this country. Our present standard was not what it ought to be. If it was, and the time ever came when we had to have soldiers and sailors, we would have a finer and better body of men to go against the enemy. We of this generation must not die leaving our children unprepared for this eventuality. There had been a tendency to ridicule the inflexible rules that controlled the acceptance of men for military or naval service. There were good reasons for the severity of these demands. The psychiatrist had kept many a lad out of the army who could get on fairly well in civil life but was unfit for the strain of military service, and in that way had saved the Government much in the way of pensions. That there should have been so many of our boys with such defects showed something wrong with our national life, and the conditions under which these children were brought up which were responsible for defective nervous systems and lack of inhibition which bred epilepsy, mental defectiveness, and degenerates. In 1918, there were rejected from the navy and marine service 37,000 young men for defects of vision and 5,000 for defective hearing. Those who had been threatened by submarines did not want a man on the bridge with defective eyesight or a man below taking soundings with defective hearing. That there were such a large number of young men with defective eyesight and hearing was not primarily the fault of the aurist or the oculist. There would not be so many of these defects were the parent indoctrinated on the subject of proper lighting and if the school authorities saw that schools were properly illuminated and textbooks printed in proper type and on paper not too highly glazed. It should be remembered that every myopic and every astigmatic was handicapped not only from the military standpoint but in his civilian pursuits. The speaker then dwelt briefly on the problem offered by the man with functional heart condition, and said he was often more troublesome in the army than the man with a real heart lesion. In speaking of the work of the army and navy in reducing venereal disease, he expressed the hope that this problem would not be laid aside with the return of the soldiers and sailors to civil life. He confessed that he had no panacea to offer. Segregation, prophylaxis, and sex education all had their merits, but he could venture no specific suggestion; but if we allowed this problem to fall into the background we would be guilty of a grave crime.

Dr. C. C. Pierce of the United States Public Health Service of Washington, D. C., spoke as the representative of Surgeon General Blue, outlining briefly the activities of the Public Health Service in connection with the war. He stated that just after the war was declared the President issued an executive order making the Public Health Service a part of the military establishment. This did not change the administration of the Public Health Department; it merely made available for war purposes the personnel, stations, and equipment of the service. Certain men were assigned to duty in the army and navy. The personnel of the Hygienic Laboratory was engaged in war work, during the entire period of the war, manufacturing increased amounts of serums, antitoxins, and vaccines. Enormous quantities of antityphoid vaccine were produced for use among the civilian population and in areas adjacent to cantonments. Others were assigned to munition plants to avoid the effects of noxious materials used in the manufacture of explosives. The Public Health Service established sanitary zones around cantonments in fifty-three different localities, and in connection with this work had cooperated with and strengthened local health organizations. This work included all phases of sanitation, water, food, the milk supply, the elimination of insects and flies, the control of communicable diseases, and this included venereal diseases. In this extra-cantonment work the great achievement was the control of malaria. They had eradicated the mosquito from areas totaling altogether more than ten times the area of the canal zone. Malaria during the war had been a negligible disease in the army, and the number of lives saved among the civilian population was also great; the statistics on this subject were now being tabulated and would soon be available. They had demonstrated that the control of malaria was feasible as a part of the work of a local health agency, either city, county, or State. The speaker described the reorganization of the Interdepartmental Hygiene Board and described the work of this organization directed toward the control of venereal disease. This work was now established in forty-four States. There was a general feeling among the officers of the army, navy, and public health service that never again would they go back to the pre-war days as regarded the question of venereal diseases and allow this skeleton in the closet. The public health service now had charge of the war risk patients and hospitals were being provided for them.

Dr. Livingston Farrand spoke for the American Red Cross. He said that the Red Cross occupied a peculiarly advantageous position. It had its official connections and official association. It was official when it wanted to be and it could be unofficial when an occasion arose that made such a course necessary. For that reason it had been a particularly useful agent. It was the agency through which the American people had been able to express their cooperation with the army and navy. The most striking thing had been the perfectly stupendous outpouring on the part of the people. Whatever was asked for they gave at once, without question, and no one would raise an issue with the statement that the Red Cross was the agency of the people that was responsible for carrying out their wishes quickly, efficiently, and usefully. Dr. Farrand said he had seen more of the action of the Red Cross abroad than in this country. Before our army reached France it was the most powerful agency in upholding the morale of the French people and it was therefore largely responsible for winning the war. The reason of that was because the Red Cross was the only visible expression of American intervention in broad terms. It provided for the civilian needs of France and did the same thing in Italy. It had left a record and an impression in France and Italy that would never be forgotten and never would be lost. The figures in connection with the supplies furnished were astounding. It furnished a large proportion of the army nurses, about 34,000, and 19,000 of these were in active service. It furnished three hundred million surgical dressings. They were able to do all these things because the American people were back of them and because they were not handicapped by the slowness of governmental activities. Dr. Farrand also referred to the great work of the Red Cross in the camps, canteens, and hospitals of this country and stated that the task confronting that organization was as serious at this moment as when it was confronted by war. The question was how should this organized energy be directed wisely to the problems of peace. On careful consideration there was a great unanimity of opinion that this energy should be turned towards the problem of the prevention of disease, the upbuilding of health, and the maintenance of a sound morale in the several peoples of the world.

Colonel Harry B. Birmingham of the Medical Corps of the United States Army made this address as the representative of the Association of Military Surgeons, in which he said that at no time in the history of the American Medical Association was there such a variety of important and interesting questions as those before them at the conclusion of this great war. For the military surgeon the war was not without its lessons. The greatest of these was the knowledge of the state of unpreparedness and this fell very heavily on the medical men. It was a well known biological fact that aggregations were inimical to life and this was true of the human species. The practical side of the question

for the medical man was how to preserve the life and efficiency of the soldier from the moment of his mobilization. That they had succeeded as well as they had was due to their unfailing patriotism, loyalty, and self-sacrifice shown by the members of the medical profession. It was a matter of congratulation that we had an organization like the American Medical Association to assist in the mobilization of the medical forces, but they had something even more concrete than that. They had the Association of Military Surgeons, composed of men in the regular army, navy, and Public Health Service. He felt sure that if Nicolas Senn had lived he would have found a way to have coordinated the work of some of these different organizations during the war. He spoke of the glory attached to the service and the fact that the military experience was one which no red-blooded man wanted to part with. He said that naturally a man wanted to identify himself with an association of military surgeons and make it a true military organization, having on its rolls every man who had been in the military service. This organization now had a membership of 9,000, and it would be interesting if every man who was eligible would help to perfect it as the great representative medical military body of the great war.

Dr. Lee Frankel of the American Health Association spoke of the work done by the men who were left at home and were bereft of the glamour of war. These men and women who had remained at home and had worked as sanitarians, bacteriologists, hygienists, and public health nurses, were equally entitled to some recognition. They were the men who inspected sewers, looked after garbage disposal, studied the noxious vapors found in the air that had been breathed, and many other problems concerned with the health of the people. They, too, deserved a tribute of regard and esteem. The great war was over, but the war which these men were waging was just begun; this was the great war in which this Association had been engaged ever since its existence. It was combating a foe greater than that on the other side, one whose nature it did not understand. The men who represented this work were the same type of men as those who had wiped out yellow fever, reduced the incidence of typhoid fever, and were engaged in solving the problems of preventive medicine. There were in this country a hundred million people who did not know how to protect their health. We should have a Federal organization looking after the health of the people. We had spent billions of dollars for defense; if we came to the realization that billions and billions should be spent on the health of the people, we might reach such a stage that when this Association met there would be nothing left to discuss but how to spend our mature old age.

Dr. David R. Lyman of Wallingford, Conn., spoke for the National Tuberculosis Association. He said the war had taught them much in regard to nervous disease, vascular disturbances, venereal disease, etc., but had they known as much four years ago as they did now they might have taken advantage of the experience offered in the draft boards to have accumulated an amount of information such as they would never again get in this generation. The National Tuberculosis Association had done its best to reclaim this lost opportunity. There were rejected by the draft boards because of tuberculosis 61,954 men. The eyes of the tuberculosis worker were now open and if there should be another war he would be prepared to take advantage of the opportunity for study that it would offer. The message he particularly wished to emphasize was that we must have universal military service and we must have it primarily as a health measure. It was the duty of the physicians and surgeons of America to do what they could to get universal military service. The active participation of two and a half million men in military operations had given a new vision of personal and public hygiene, a new sense of personal responsibility, and a new sense of discipline. What greater backing could such a movement have than that of a united medical profession in America. Our young men should have six months of intensive training in a government camp in their own State and physical records of these men should be kept on file in the office of the United States Public Health Service and in the State Department of Health. We should have energetic action on the part of the State and local medical societies as well as of the American Medical Association, the newspapers and all other means of reaching the people and demonstrating to them the value of universal military service. This would be the greatest of all public health measures, and if the medical profession was instrumental in bringing it about it would have rendered the greatest service that any body of men had ever rendered to their country.

Dr. Franklin Martin, as the representative of the American College of Surgeons, spoke of the organization of the body, which had been patterned after the Royal College of Surgeons in England. They now had a membership of 4,000 in this country and 400 in Canada. As to the work of the American College of Surgeons in the war, in 1916 the secretary of the American College of Surgeons was asked by the Surgeon General to present a list of the membership under 55 years of age who would be available for the Medical Reserve Corps. Within two weeks that list was furnished and within two months committees from the American College of Surgeons, the Clinical Congress of Surgeons, and the Congress of American Surgeons had associated to present plans for offering the assistance of the American medical profession for service in the war. He described more in detail how the medical men were furnished to the different departments of the service and described the work done by the Medical Advisory Committee of the Council on National Defense. He said it was difficult for him to discriminate between the work done by the American College of Surgeons and these other bodies. They had done everything the Government had asked, after due consideration, and the Government never asked anything until it had consulted with the General Medical Board consisting of the Surgeon Generals of the Army, Navy and Public Health Service and representatives of the Medical Advisory Board of the Council on National Defense. When these agreed to a policy, the Government carried out that policy. After having furnished to the Army, Navy and Public Health Service the quota of men required, the Medical Advisory Board of the Council on National Defense organized the Volunteer Medical Service Corps among the physicians of this country. Those who joined this organization agreed to serve wherever they could and at any time they could and to do such work as they were fitted to do. The records of 60,000 medical men were now complete and filed under the Holworth system. These records were of great value and had been asked for by the Surgeon General's Office where they would be placed on file so that in any emergency in peace or war a suitable quota of medical men could be supplied on very short notice. When these records were complete they would give the data concerning 75,000 physicians. These 75,000 men in addition to the thirty or forty thousand in military service gave a total of 115,000 of the 130,000 medical men in this country. There was still something to be done. When asked to join the Voluntary Reserve Corps a man should not stand back because of some slight irritation that he had experienced during the time of war, but should place himself where he could be of service to his country when needed.

ELECTION OF OFFICERS.

President, Surgeon General W. C. Braisted, U. S. Navy; *First Vice-President*, D. L. Edsall, Boston; *Second Vice-President*, Emery Marvel, Atlantic City; *Third Vice-President*, Eugene S. Talbot, Chicago; *Fourth Vice-President*, George H. Kress, Los Angeles; *Secretary*, Alexander R. Craig, Chicago; *Treasurer*, William Allen Pusey, Chicago; *Speaker of House of Delegates*, Hubert Work, Pueblo, Colo.; *Vice-Speaker*, Dwight H. Murray, Syracuse, N. Y.; *Trustees*, Archibald Dowling, Shreveport, La., A. R. Mitchell, Lincoln, Neb., D. C. Brown, Danbury, Conn.; *Judicial Council*, Ira C. Chase, Ft. Worth, Tex.; *Council on Health and Public Instruction*, Haven Emerson, New York City; *Council on Medical Education*, Arthur D. Bevan, Chicago; *Council on Scientific Assembly*, J. B. Blake, Boston. Next Place of Meeting, New Orleans, La.

MEDICAL VETERANS OF THE WORLD WAR.

An organization with this title was founded with the following officers: *President*, Victor C. Vaughan; *Vice-President*, Admiral E. R. Stitt, M.C., U.S.N.; *Secretary and Treasurer*, S. F. Russell.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Ohio State Board of Medical Examiners.

December, 1918

ANATOMY.

1. Into what regions is the abdominal cavity divided? Name each and describe its contents.
2. Describe the platysma myoid muscle. What relation has this muscle to the external jugular vein?
3. How is the spinal cord divided by regions? How is it divided longitudinally?
4. What are the ventricles of the brain and how are they formed? What is above the lateral ventricle?
5. How are the branches of the pulmonary artery arranged with regard to the aorta? Where is their ultimate distribution?

PHYSIOLOGY.

1. Describe the process of coagulation of the blood.
2. What effect is produced on the heart's action by stimulation of the cardio-inhibitory center?
3. How is the diaphragm affected in expiration?
4. What are the uses of (*a*) saliva, (*b*) trypsin, and (*c*) amylopsin?
5. Into what general classes are foods divided? Give examples of each class.
6. What is meant by diffusion and osmosis? Give examples in the human economy.
7. What variations of temperature are found in the different parts of the body? Mention the reasons for such variations.
8. What is rigor mortis? Order of its appearance?
9. What is the composition of normal urine?
10. What are the functions of the pneumogastric nerve?

CHEMISTRY.

1. What is chloroform, chemically, and how is it made?
2. Define an alkaloid and name three principal ones used in medicine.
3. How does urea originate in the body? In what morbid conditions is the amount of urea diminished, and in what increased?
4. Describe two tests for glucose.
5. What is the reaction of normal gastric juice, and to what is it due?

MATERIA MEDICA AND THERAPEUTICS.

1. What are the uses of narcotics? Name the principal ones and give doses.
2. Name two diseases in which you would use a serum. Name the serum, dose, and mode of administration.
3. Give indication and dosage of ipecac, quinine, and salol.
4. Name three potassium salts; give use and dose of each.
5. Sodium nitrate—physiological action, use, and dose. Digitalis—physiological action, use, and dose.
6. Explain the action and use of diuretics.
7. What is the common name of magnesium sulphate? Give action, use, and dose.
8. Give some indication for the use of arsenic. In what forms may it be used and give dose of each.
9. Atropine: source, physiological action, and use.
10. When would you apply heat and cold? How used and action of each?

BACTERIOLOGY, PATHOLOGY, AND HYGIENE.

1. Define the terms used therapeutically:—vaccine, antitoxin, and serum. Illustrate.
2. Describe a tuberculin test; in what way may it be employed and what does it indicate?
3. Describe the bacillus of Pfeiffer and differentiate it from the pneumococcus.
4. Describe the cardiac pathological processes preceding a decompensated heart.
5. Describe the production of a tuberculous cavity in the lung tissue.
6. Name and differentiate pathologically different forms of enlarged prostate.
7. What steps would you take to locate the source of infection in a typhoid fever epidemic, where there is reason to believe it has arisen through the milk supply?
8. What measures should a health officer take in a diphtheria epidemic?
9. When may a water supply be declared safe for general community use?
10. Name the principal quarantinable diseases and name the rules for determining the time of quarantine for each.

ANSWERS.

ANATOMY.

1. The regions of the abdomen and their contents are shown in the following table. It is to be remembered that the contents will vary according to the position of the lines drawn; these are arbitrary, and nearly every writer differs from every other. In the following table the superior horizontal line extends between the cartilaginous ends of the tenth ribs, the inferior between the anterior superior iliac spines. The vertical lines pass upward from the iliopectineal eminences, at right angles to the upper horizontal line.

The viscera situated in each region are as follows:

RIGHT HYPOCHONDRIAC.	EPIGASTRIC	LEFT HYPOCHONDRIAC.
Liver.	Liver.	Stomach.
Right kidney.	Stomach.	Spleen.
Hepatic flexure of the colon.	Gall-bladder.	Left kidney.
	Duodenum.	Splenic flexure of the colon.
	Pancreas.	
RIGHT LUMBAR	UMBILICAL	LEFT LUMBAR.
Right kidney.	Transverse colon.	Small part of left kidney.
Ascending colon.	Duodenum and small intestines.	Descending colon.
Ileum.	Great omentum.	Small intestines.
RIGHT ILIAC.	HYPOGASTRIC.	LEFT ILIAC.
Cecum.	Small intestines.	Sigmoid colon.
Appendix.	Bladder in children.	Small intestines.
Last coil of ileum.	Distended bladder in adults.	
	Pregnant uterus.	
	Sigmoid colon.	

2. The *platysma myoid* muscle is a thin muscular sheet embedded in the superficial fascia which covers the deltoid and pectoralis major muscles at their clavicular attachments. The muscle is inserted into the outer part of the lower border of the mandible, and into the angle of the mouth. It draws the mouth downward and outward, slightly raises the skin of the upper part of the chest, and is a slight depressor of the mandible. It covers the external jugular vein.

3. The *spinal cord* is divided into regions, as follows: Cervical, dorsal or thoracic, lumbar and sacral.

Longitudinally, it is divided into two halves by the anterior and posterior median fissures; these halves are united in the center by the commisure. These lateral halves are also subdivided by the antero-lateral and postero-lateral fissures into anterior, lateral and posterior columns.

4. The ventricles of the brain are five distinct cavities, between the first four of which there is an intercommunication. The *first two*, called the right and left lateral ventricles, are situated within the substance of the cerebral hemispheres; they are separated by the septum lucidum, and communicate with the third ventricle by the foramen of Munro. The *third ventricle* is situated between the optic thalami, at the base of the brain; it communicates by the aqueduct of Sylvius with the fourth ventricle. The *fourth ventricle* is between the medulla and cerebellum. The *fifth ventricle* is between the two layers of the septum lucidum, and is therefore between the two lateral ventricles. It is covered over by the corpus callosum.

The lateral ventricles are covered by the corpus callosum.

5. The *right pulmonary artery* passes behind the

ascending aorta and goes to the root of the right lung, where it divides into two branches, the upper being distributed to the upper lobe, and the lower to the middle and lower lobes.

The *left pulmonary artery* passes in front of the descending aorta, and goes to the root of the left lung, where it divides into two branches, the upper being distributed to the upper lobe, and the lower to the lower lobe.

PHYSIOLOGY.

1. *Coagulation of the Blood.*—When blood is withdrawn from the blood-vessels of the living body it first becomes viscid, then sets, and is converted into a jelly-like mass. This is due to the formation of fibrin. The jelly contracts, forming the clot; and at the same time the serum is squeezed out from the clot. Various circumstances and conditions will hasten or delay the process of coagulation. In man, the blood generally becomes viscid in from two to three minutes; it forms the jelly-like mass in from five to six minutes; a few minutes later the serum begins to appear; and the whole process is completed in from twenty-four to thirty-six hours. The clot then floats in the serum. The process is thus summed up by Halliburton. From the platelets, and to a lesser degree from the leucocytes, a material is shed out called *thrombogen;* from the formed elements of the blood, but also from the tissues over which the escaping blood flows, is shed out an activating agent, called *thrombokinase.* In the presence of *calcium* salts, thrombokinase activates thrombogen in such a way that an active enzyme is produced, which is called *thrombin.* In the blood plasma a protein substance exists, called *fibrinogen.* Thrombin acts on fibrinogen in such a way that it is transformed into the insoluble stringy material which is called *fibrin;* this entangles the corpuscles and forms the clot.

2. Effect produced on the heart's action by stimulation of the cardio-inhibitory center: The heart's action is slowed, and may be entirely stopped. It is a tonically active center, that is, it acts continuously.

3. The diaphragm has no active part to play in expiration; but it is passively pushed upward into the thoracic cavity by the contraction of the abdominal muscles.

4. The *uses of the saliva* are: (1) To moisten the mouth, (2) to assist in the solution of the soluble portions of the food, and thus (3) to administer to the sense of taste, (4) to lubricate the bolus of food, and thus (5) to facilitate the acts of mastication and deglutition, and (6) to change starches into dextrin and sugar.

The *use of trypsin* is to change proteins into proteoses and peptones, and afterwards decompose them into polypeptides and aminoacids (in an alkaline medium).

The *use of amylopsin* is to convert starches into maltose.

5. *Foods are classified:*

I. Inorganic. { Water. / Salts.

II. Organic. { Non-nitrogenous { Carbohydrates. / Fats. / Nitrogenous—Proteins.

Examples of each: *Carbohydrate*, sugar and starches: *Fat*, fat of meat, and butter: *Protein*, flesh of animals, and white of eggs; *Salt*, sodium chloride, and calcium phosphate.

The *carbohydrates* consist of carbon, hydrogen and oxygen, the two latter being in the proportion to form water. *Fats* consist of carbon, hydrogen, and oxygen, the proportion of oxygen being less than sufficient to convert all the hydrogen into water. *Proteins* consist of carbon, hydrogen, oxygen, nitrogen, sulphur, and sometimes other elements.

6. "The term *diffusion* has long been applied to the regular mixing of the molecules of two gases when brought into contact in a confined space. More recently it has been applied to the mixing of the molecules of two solutions when brought into contact. If, however, the two solutions are separated by a membrane, permeable to the solutions, diffusion will still occur. To this form of diffusion the term *Osmosis* has been applied in the case of water, and *Dialysis* in the case of diffusible substances. All bodies can be divided into two groups, *crystalloids* and *colloids.* To the former group belong bodies having a crystalline form, which readily go into solution in water. All such bodies are diffusible (dialyzable), their power of dialysis, however, varying considerably. To the second group belong such bodies as have no crystalline form (amorphous). These are generally bodies with a large molecule, which form colloidal suspensions in water, and are only slightly or not at all diffusible. An exception to this second group is hemoglobin, which has a very large molecule but is crystalline and is diffusible."—(Kirkes' *Physiology.*)

Physiological applications: "In the animal body the fluids are separated by delicate membranes across which the constituents of the fluids, inorganic and organic, are continually passing. Thus prepared foods in the intestine pass across the intestinal wall into the blood and lymph-vessels; the constituents of the blood pass across the wall of the capillary vessel into the tissue spaces, from which they pass (*a*) through the walls of various glands to take part in the formation of their secretion; (*b*) across the sarcolemma into the interior of the muscle fiber; (*c*) across the limiting surface of and into the interior of all tissue cells. The waste products, the results of tissue and food metabolism, pass from the interior of cells across their limiting membranes or surfaces into the tissue spaces; thence across the wall of the capillary vessel and the epithelium of the lung, the kidney, the liver, etc., to take part in the formation of the excretions. These and other processes are believed to be accomplished by the factors, diffusion, osmosis, and filtration."—(Brubaker's *Physiology.*)

7. The normal temperature of the body is between 98° and 99° Fahr. But the temperature of the skin is lower than that of the mouth or rectum; because heat is lost from skin by evaporation and radiation. The temperature of the blood from the liver is higher than in other parts of the body, owing to the active metabolism occurring in the liver.

8. *Rigor mortis* is a condition of rigidity assumed by the muscles after death. It is supposed to be due to the coagulation of the myosinogen. The muscles lose their irritability and pass into a condition of contraction. Heat is evolved, carbon dioxide is given off, and the muscles become acid in reaction due to the development of sarcolactic acid. Rigor mortis usually sets in first in the muscles of the lower jaw, face, and neck, then in those of the thorax, abdomen, upper extremity and lower extremity. It usually lasts for from twenty-four to forty-eight hours, and disappears in the same order as the onset.

9. *Composition of normal urine:*

	(PARTS IN 1000.)	
Water	950.00	
Urea	28.00	Organic matter, 37.60
Uric acid	0.60	
Hippuric acid	0.35	
Creatinin	0.65	
Extractives	8.00	
Sodium chloride	8.00	Inorganic matter, 12.40
Phosphoric acid	2.00	
Sulphuric acid	1.25	
Lime (CaO)	0.25	
Magnesia (MgO)	0.30	
Potash (K_2O) and soda (Na_2O)	0.60	
Total	1000.00	

10. *Physiological action of the pneumogastric nerve:* "Throughout its whole course the vagus contains both sensory and motor fibers. To summarize the many functions of this nerve . . . it may be said that it supplies (1) *motor* influence to the pharynx and esophagus, stomach, and intestines, to the larynx, trachea, bronchi, and lungs; (2) *sensory* and, in part, (3) *vasomotor* influence, to the same regions; (4) *inhibitory* influence to the *heart;* (5) *inhibitory* afferent impulses to the *vasomotor center;* (6) *excito-secretory* to the salivary glands; (7) *excitomotor* in coughing, vomiting, etc."—(Kirkes' *Physiology.*)

CHEMISTRY.

1. Chemically, chloroform is trichlormethane, $CHCl_3$. It may be made by heating chloral hydrate with an alkali: $C_2HCl_3(OH)_2 + KOH = CHCl_3 + HCOOK + H_2O$.

2. *Alkaloids* are organic, basic, nitrogenous substances, alkaline in reaction, and capable of combining with acids in the same way that ammonia does.

Three alkaloids used in medicine: Strychnine, atropine, and morphine.

3. Urea originates in the body from the protein substances in the body and in the food ingested. The proteins ingested become changed into proteoses, peptones, polypeptides, and amino-acids; these last are split up into ammonia, and this is oxidized to become urea.

The *urea in the body is diminished* in old age, starvation, and conditions which interfere with the ordinary processes of protein digestion.

The *urea is increased* when much water is ingested, in the early stages of fevers, in diabetes, and in chronic nephritis.

4. *Two tests for glucose:* (1) *Fehling's test for glucose:* Place in a test-tube a few c.c. of the liquid prepared as stated below, and boil; no reddish tinge should be observable, even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of *traces* of glucose, only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out.

[The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34,653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c.; and Solution II of 130 gms. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

(2) A solution containing glucose, if heated with a strong solution of potassium hydroxide, gives a brown color and an odor of burning caramel.

5. The reaction of normal gastric juice is acid, due to hydrochloric acid.

MATERIA MEDICA AND THERAPEUTICS.

1. *Uses of narcotics:* To induce sleep; to allay pain, irritation, spasm, nervous agitation and unrest; to lower morbidly acute perception. The *principal narcotics (with dose)* are: Opium, ½ to 2 grains; chloral, 10 to 20 grains; belladonna, 1 to 5 grains, of the leaves; hyoscyamus, 7 to 15 grains; cannabis indica, 2 to 4 grains; lupulin, 10 to 25 grains; stramonium, 3 grains; alcohol, and the anesthetics.

2. A serum may be used in diphtheria and tetanus.

In *diphtheria*, the serum antidiphthericum is indicated; 1,000 units may be given as an immunizing or prophylactic dose, and from 5,000 to 20,000 units as a curative dose; this latter is to be repeated if necessary. It should be injected into the loose subcutaneous tissue of the back.

In *tetanus*, the serum antitetanicum may be used; the immunizing dose is 1,500 units, subcutaneously; as a curative agent, 3,000 to 5,000 units may be given by subdural injection, followed by 10,000 units intravenously.

3. IPECAC. *Indications:* As an emetic, to clear the respiratory passages, to relieve the stomach, in bronchitis, emphysema, dysentery, and jaundice, and as a diaphoretic in rheumatism. *Dose*, as an emetic, 15 grains; for other purposes, 1 grain.

QUININE. *Indications:* In malaria; as a tonic; in influenza, in dyspepsia, in asthma; as an antipyretic; and locally, for sores in diphtheria, and in hay fever. *Dose*, 15 grains at the time of the chill in malaria; in other cases about 4 grains.

SALOL. *Dose:* gr. vijss. *Indications for use:* As a disinfectant, in inflammations of mouth and pharynx, in cystitis, as an intestinal antiseptic in typhoid fever, in muscular rheumatism, in intestinal indigestion and fermentation, in cholera. In the stomach it is subdivided into salicylic acid and carbolic acid.

4. POTASSIUM SALTS. The *bicarbonate* is used for itching and for skin diseases; also for dyspepsia, rheumatism, gout, jaundice, and gallstones. The *acetate* and *citrate* are used for gout, rheumatism, in dropsy, renal diseases, cardiac diseases, and in general as diuretics. The *sulphate* and *bitartrate* are used as cathartics, the latter also as a diuretic. The *dose* of the bicarbonate is 30 grains; citrate, 15 grains; sulphate and bitartrate, 30 grains.

5. SODIUM NITRITE. *Action:* Causes a fall in blood-pressure, stimulates respiration, then depresses it. *Used* in angina pectoris, high arterial tension, cardiac dyspnea, epilepsy, and as an anti-spasmodic. *Dose*, one grain.

DIGITALIS. *Physiological action:* It is a gastro-intestinal irritant, it slows the rate of the heart, prolongs diastole, increases the force of the heart, it contracts the blood-vessels, and causes a rise in blood pressure, it also acts as a diuretic. *Therapeutic use:* Digitalis is indicated in diseases of the heart: (1) when the heart action is rapid and feeble, with low arterial tension; (2) in mitral lesions when compensation has begun to fail; (3) in non-valvular cardiac affections; (4) in irritable heart, due to nerve exhaustion. Digitalis is *contraindicated* in diseases of the heart; (1) in aortic lesions when uncombined with mitral lesions; (2) when the heart action is strong, and arterial tension high. Digitalis is also a diuretic; and it is also used in some forms of nephritis, exophthalmic goiter, pneumonia, chronic bronchitis, etc. *Dangers: Overdose or constant use* will cause irregularity of the heart, headache, vomiting, and hobbling dicrotic pulse, particularly when the patient changes from the recumbent to a sitting posture. *Dose:* Of the tincture, 15 minims.

6. DIURETICS *act:*—(1) By increasing the action of the heart or by contracting the intestinal and other vessels, thus raising the general blood-pressure. (2) By dilating the afferent renal vessels, thereby increasing the renal blood supply and raising the pressure in the glomeruli. (3) By contracting the efferent vessels, raising the pressure in the glomeruli and lessening absorption in the tubules, or both. (4) By stimulating the secreting cells or nerves of the kidneys. (5) By flushing the kidneys, as by the ingestion of water in large quantity.

Diuretics are *employed in medicine* for certain definite purposes, as follows:—to remove fluid from the tissues and cavities of the body in cases of dropsy; to promote the elimination of waste-products and other poisons from the blood; to maintain the action of the kidneys; to dilute the urine, and to alter morbid conditions of that excretion.—(From Potter's *Materia Medica.*)

7. MAGNESIUM SULPHATE. *Common name*, Epsom Salt. *Action:* Saline cathartic. *Use:* As a purgative, also used in dropsy, inflammatory conditions, constipation, portal obstruction, increased blood pressure in the brain; locally it has been used as an application in erysipelas or orchitis. *Dose*, 3 or 4 drams.

8. *Indications for the use of arsenic:*—"Arsenous acid was formerly much used as a caustic for destroying growths of various kinds. In commencing a course of arsenical treatment the dose at first should always be small, and it is important that as a rule the drug should be taken after meals. In some cases of vomiting and of irritative dyspepsia, however, it is preferable to give it before eating. Arsenic is useful to improve the digestion and general nutrition, and may be of service in gastric ulcer and cancer, and some forms of diarrhea. Next to quinine, arsenic is the most reliable remedy for malarial infection, and it is often valuable in anemia and chlorosis and in nervous disorders, especially chorea. In chronic bronchitis and other respiratory disorders and in some cases of organic heart disease it is also beneficial. One of its most useful and general applications is in the treatment of cutaneous affections of many varieties, especially when the acute inflammatory stage is past. Cacodylic acid and sodium cacodylate have recently been brought forward as eligible methods for the administration of arsenic: their solubility, relatively small toxicity, and the diminished local irritation which they produce are advantages to be borne in mind."—(Wilcox's *Materia Medica.*)

Some preparations with doses:—Arseni iodidum, 1/12 grain; arseni trioxidum, 1/30 grain; liquor potassii arsenitis, 3 minims; liquor sodii arsenatis, 3 minims; sodii arsenas 1/12 grain; sodii cacodylas, 1 grain.

9. ATROPINE. *Source:* — The *Atropa Belladonna*, belladonna plant, or deadly nightshade.

Physiological action: anodyne, mydriatic, inhibits secretions, depressant of terminations of nerves, accelerates the heart beat, causes rise in blood pressure, but toxic doses cause the blood pressure to fall, stimulates the respiratory center, but large doses depress the same; it may cause vertigo, restlessness, excitement, delirium, or mania.

Therapeutic indications: To relieve pain, relax spasm, check sweating, as a mydriatic, for night sweats, to check griping of purgatives; in asthma, to check fevers, in heart disease, shock and collapse, acute coryza, urinary incontinence, chordee, low delirium of fevers, mania, alcoholism; as an antigalactagogue, spasmodic cough.

10. THERAPEUTICS OF HEAT.—"As a local application in many *acute inflammatory diseases*. Generally, it may be used interchangeably with cold, the chief guide in the selection of one or the other being the feelings of the patient. Moist heat in the form of fomentations or hot baths is a valuable adjuvant to morphine in relaxing the spasm of *unstriped muscles* which occurs in *intestinal, biliary* and *nephritic colics*, in *spasmodic croup*, and in *retention of urine*. Hot baths are also useful in breaking up *general convulsions*, especially those occurring in children. Hot footbaths, through their reflex effect upon the circulation, often afford relief in *cerebral congestion, acute coryza*, and *amenorrhea from exposure to cold*. In *acute and chronic parenchymatous nephritis* hot-air baths, hot-packs and hot-water baths are of the greatest service in producing diaphoresis, especially when there is dropsy or uremia. Warm effervescent baths are useful in certain cases of *chronic heart-disease*. The continuous immersion of the patient in a warm bath (90°-100° F.) has been found useful in *extensive burns* and in some cases of *phagedena*. A course of Turkish baths is frequently beneficial in *chronic gout*, in *chronic rheumatism*, and in the early stages of *chronic Bright's disease* and *diabetes*.

"In conditions attended with subnormal temperature, such as *surgical shock* and *collapse from disease* or *poisoning*, the general application of heat, especially in the form of the hot bath, is the most important factor of the treatment.

"The local application of intense dry heat (250°-350° F.) is often very advantageous in certain affections of the joints, especially in *chronic synovitis, traumatic arthritis, sprains, tendinous inflammations*, and in the after-treatment of *fractures* and *luxations*. In *subacute* and *chronic rheumatism* it is also occasionally useful, but in *rheumatoid arthritis* it is of little value."

THERAPEUTICS OF COLD.—"In the early stage of *acute inflammation*, especially that resulting from traumatism, a cold-water dressing often acts most happily. In *diphtheria, scarlet fever* and *acute tonsillitis* the application of cold compresses or of an ice-bag to the throat generally affords more relief than poultices or fomentations. In *chilblain* or *frost-bite* the intensity of the reaction should be moderated by rubbing the part with snow or ice. In *croupous pneumonia*, when the temperature is high and the pulse strong, an ice-bag or an ice-poultice adjusted over the affected lung reduces the fever, allays the pain, and quiets the patient. In *acute dysentery* ice-suppositories inserted for a length of time, one after another, are very useful in allaying tenesmus. An ice-cap or an ice-bag may be applied to the head with advantage in *meningitis, apoplexy, cerebral congestion, headache*, and the *delirium of fevers*. In *neuralgia* dry cold sometimes affords temporary relief, but, as a rule, heat is more grateful. In *exophthalmic goiter, paroxysmal tachycardia* and *symptomatic palpitation* an ice-bag or a Leiter's coil over the precordia often exerts a sedative influence upon the heart. An ice-bag may also temporarily relieve distress in *aortic aneurysm*, especially when the sac is superficial. In *internal hemorrhage* the application of an ice-bag over the affected region is a useful adjuvant to other measures. Cold bathing is also indicated in *typhoid* and other *continued fevers*."

(From Stevens' *Materia Medica and Therapeutics.*)

BACTERIOLOGY, PATHOLOGY, AND HYGIENE.

1. An *antitoxin* is a substance formed in the body, of a protective character, and capable of rendering inert the poisonous products of bacteria.

"A *serum* is a product obtained by injecting into an animal, usually a horse, a culture (*e.g.* Diphtheria) or the toxin from a culture (*e.g.* Streptococcus) of the organism. Serums may be divided into—(a) *Antitoxic serums*, such as Diphtheria and Tetanus, which are obtained by injecting filtered cultures into the animal used to provide the serum. (b) *Anti-bacterial serums*, such as Anti-Streptococcus and Anti-Gonococcus, in the preparation of which unfiltered cultures are used. Serums are usually injected in the flank or between the shoulder blades, the skin having previously been cleansed and the syringe carefully sterilized. Cases are on record where they have been given intravenously with normal saline solution and also per rectum.

"A *vaccine* is a finely divided suspension of killed cultures of a microorganism which is injected directly into the human subject. The object is to stimulate the individual to elaborate his own antibodies, which results in increased resistance to the ravages of bacterial infection. Vaccines are of two kinds—(a) *Autogenous*—prepared from the organism isolated from pathological material taken from the patient. (b) *Stock* prepared from virulent cultures of the organism, isolated from other cases of similar bacterial origin. Vaccines are administered by subcutaneous injection by means of an all-glass hypodermic syringe. The site of injection may be the flank, thigh, shoulder, or back. The skin is first sterilized by a pledget of cotton wool saturated with a suitable antiseptic, *e.g.* lysol.

"Briefly, the difference is that with a serum the opposing influence to the toxins is produced outside the human body, while with the vaccine it is produced inside and the degree of immunity conferred is greater with the latter than the former. It should also be noted that the dose of a serum is much higher, from the standpoint of the amount of fluid injected, than in the case of a vaccine. With the former the dose usually ranges from 10 c.c. to 50 c.c., while with the latter it is, as a rule, not more than 1 c.c." (Holland's *Pharmacy Handbook.*)

2. "The *tuberculin reaction* has been made a cardinal feature in the diagnosis of tuberculosis in cattle, and to some extent in man. Its chief practical application is in detecting the disease in dairy cows. The test on cows is made by injecting subcutaneously from 20 to 40 centigrams of tuberculin and noting any change in the temperature of the suspected animal. The normal temperature should be taken every two hours on the day prior to the injection, and after the injection should be taken on that day and on the following day at least every two hours. The normal temperature of the cow may vary considerably, and should always first be determined; a rise of from 1.5° to 3° C. warrants the inference that the animal is tuberculous; the tuberculin reaction has been often controlled by autopsy, and for all practical purposes is specific and unequivocal. The information afforded by a positive outcome, as a rule can be relied on implicitly, but a negative reaction is not always proof of the absence of infection. Failure of the test is most likely to occur in advanced and clinically recognizable cases." —(Jordan's *Bacteriology.*)

3. The *Bacillus influenzæ* is a small bacillus, about 0.5 mikron long and 0.2 mikron wide; it has rounded ends, is non-motile, does not form spores, is Gram negative, stains with Loeffler's methylene blue but not readily with the usual anilin dyes, it is aerobic and is difficult to cultivate.

The *pneumococcus* (of Friedlander) is an encapsulated bacillus of variable length, non-motile, non-flagellated, aerobic and optionally anaerobic, non-liquefying, and pathogenic; it stains with the ordinary anilin dyes, but does not retain the color when stained by Gram's method. Its form is so variable that it has been described by different writers as a coccus or a bacillus.

A differentiation may be made by examining stained preparations of the sputum.

4. *Preceding (and accompanying) decompensation,* there will be found reduced arterial tension, cardiac hypertrophy and dilatation, increased venous pressure; later the arterial tension may be increased, and dilatation may replace the hypertrophy; the heart is poorly nourished, receiving less arterial blood and becoming congested with venous blood; the heart loses tone, and its rhythm becomes disturbed; it becomes the seat of degenerative changes.

5. *Formation of a tuberculous cavity in the lung:* "The anatomical lesion, the tubercle, first appears as a grayish-white, translucent, semisolid granulation, about the size of a millet-seed, usually deposited in the walls of the bronchioles or around the small blood-vessels. From its presence in these situations it induces a low form of inflammation which ultimately results in its destruction. The tubercles then undergo softening or cheesy necrosis with the formation of cavities and consequent destruction of lung-tissue. The small tubercles may coalesce, forming larger nodules, or diffuse tuberculous infiltration."—(Hughes' *Practice of Medicine.*)

6. *Different forms of enlarged prostate.* "It is possible to recognize at least two forms of prostatic hypertrophy depending upon whether the new tissue is composed of elements derived from (a) the interstitial tissues or (b) the epithelial or glandular substance; organs in which both structures participate are frequently encountered, usually, however, one dominates. In the first of these groups the newly formed elements are largely unstriped muscle and fibrous tissue, histologically resembling myofibroma of the uterus. In some instances the fibrous tissue is in excess and in others the lesion appears myomatous. It is also possible to recognize circumscribed or nodose types and organs in which the lesion is diffuse. The fibrous or fibromyomatous prostate is usually firm, resists incision, the cut surfaces bulge, and are gray or grayish-white. Histologically the new tissue is composed of unstriped muscle containing more or less new fibrous tissue. The muscle cells may be in whorls, formed by multicentric grouping, or more diffuse. Cyst-like dilatations of gland spaces and areas of necrosis are sometimes present. The glandular or adenomatous type of prostatic hypertrophy gives rise to large, soft, spongy, often succulent masses which may be symmetric or nodular. Dilatation of gland spaces often results in the formation of cysts. This type has also been called parenchymatous prostatic enlargement. Histologically the condition resembles adenoma. In distended acini the epithelium is often flattened, occasionally necrotic and desquamating, sometimes in part destroyed." (Coplin's *Manual of Pathology.*)

7. A milk epidemic is characterized by the suddenness with which it makes its appearance, the sufferers being for the most part attacked at about the same time. The infected houses will be found to have been supplied, almost without exception, by the particular milk vendor whose supply is at fault; but it will occasionally happen that infected houses are discovered to which milk has been supplied by a different vendor, this circumstance being often due to the fact that the vendors on their rounds very commonly buy small quantities of milk from each other. Sometimes valuable corroborative testimony implicating the milk is forthcoming in the circumstance that some of those in the infected households who have consumed no unboiled milk, have escaped; and that households supplied from the implicated dairy, but in which no unboiled milk is consumed at all, have entirely escaped.—(Parkes' *Hygiene.*)

8. *Prophylaxis in case of diphtheria.* "Prompt isolation of sick and of suspects until bacteriological examination has shown that the disease is not diphtheria. Diphtheria is particularly well adapted to treatment in contagious disease hospitals. No one should be released from the quarantine, even if not apparently sick, until cultures taken from the throat are shown to be negative. The dead must be cared for by thorough disinfection and further prepared as directed by the health authorities before being transported for burial. The tendency of the bacilli to persist in throat and nose for long periods of time after convalescence is established should not be forgotten. All children and to a lesser degree adults who have been in contact with the disease should have swabs made and cultures taken, and if positive results are obtained, must be isolated until negative results are obtained, preferably on two successive days." (Gardner and Simonds' *Practical Sanitation*). Immunizing doses of antitoxin may also be given to those who have been exposed to infection.

9. *Potable water* should be colorless, odorless, cool, limpid, soft; it should have an agreeable taste, neither salty nor sweet nor flat; it should dissolve soap readily without formation of a curdy precipitate; it should contain not more than about twenty-five to thirty grains of solids per gallon, and should not be polluted with sewage.

The sources and varieties of water have been classified thus:

Wholesome	1. Spring water.... very palatable.	
	2. Deep-well water..	moderately palatable
	3. Upland surface water.	
Suspicious.	4. Stored rain water	
	5. Surface water from cultivated land	palatable.
Dangerous.	6. River water, to which sewage gains access.....	
	7. Shallow-well water.....	

10. *Quarantinable diseases.*—"Maritime quarantine in this country is enforced only against six diseases, viz., cholera, yellow fever, plague, typhus fever, smallpox, and leprosy. We do not quarantine against typhoid fever, tuberculosis, measles, and other infections which are not greatly feared and which are constantly with us. Infections of a non-quarantinable nature, such as scarlet fever, measles, etc., arriving at a port are permitted to enter, but must then comply with the local laws and regulations. The period of detention is based upon the usual period of incubation for each disease, and is as follows:—Cholera, 5 days; yellow fever, 5 or 6 days; plague, 7 days; typhus fever, 12 days; smallpox, 14 days; leprosy, not admitted. The time of detention is usually counted from the completion of disinfection or at least from the last possible exposure to the infection. This is usually not a very difficult matter to decide but in case of doubt the public is given the benefit." (Rosenau's *Preventive Medicine and Hygiene*).

(*To be concluded.*)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

SANE SEX LIFE AND SANE SEX LIVING. By H. W. LONG, M.D., M.R.C. Price $5 00. 157 pages. Published by Richard G. Badger, The Gorham Press, Boston Mass.

OPERATIONS OF OBSTETRICS. By F. E. LEAVITT, M.D. Price $6.00. 441 pages. Published by the C. V. Mosby Company, St. Louis, Mo.

THE SCIENCE AND ART OF DEEP BREATHING. By S. OTABE, M.B. Tokio, M.D. Bale. Price $1.75. 111 pages. Published by Wm. Wood & Co., New York, N. Y.

MALARIA, AND ITS TREATMENT. By A. C. ALPORT. Price $6.00. 267 pages. Illustrated. Published by William Wood & Co. New York, N. Y.

LA DYSCYTOGENÈSE HYPOCYTOPOÏÉTIQUE DYSEUTROPHIQUE, OU CANCER. Par Docteur NAAMÉ de Tunis. 45 pages. Published by A. Maloine et Fils, Paris.

DISEASES OF THE SKIN. By JAMES H. SEQUEIRA, M.D.Lond., F.R.C.P.Lond., F.R.C.S.Eng. Price $12.00. 622 pages. Illustrated. Published by P. Blakiston's Son & Co., Philadelphia, Pa.

OUTLOOK AND PROBLEMS OF PUBLIC HEALTH.

BY ALVAH H. DOTY, M.D.,

NEW YORK.

THE recent epidemic of influenza and the rapidity with which it spread demonstrated in a measure the lack of success of health authorities in insuring prompt and successful control of this disease. This has been shown, moreover, in outbreaks of other communicable diseases. In certain localities influenza made comparatively slow progress; in others, it extended with great rapidity and apparently was unchecked by the preventive measures employed. It cannot be expected that a disease as quickly disseminated as influenza can promptly be brought under control even by energetic action by health officials, but it is quite certain that there are means by which more satisfactory results may be obtained in dealing with influenza as well as with outbreaks of other communicable diseases. It is not my purpose to speak of influenza only, nor to deal especially with its origin or means of transmission, but rather to discuss this disease in connection with a general consideration of the measures now employed in the protection of the public health and the methods which should bring about more successful results.

There is no good reason to believe that the recent epidemic of influenza differed radically from previous ones. It is true that the lungs of those affected were often seriously involved but in none of the outbreaks, present or past, have the general characteristics of this disease been obscured by complications.

It is to be noted that histories of previous outbreaks not infrequently refer to malignant pulmonary affections with a very high mortality, which corresponds closely to reports of the recent outbreak; and previous histories refer to complications not prominent in this one. It is, therefore, not unreasonable to conclude that the course of influenza, like other communicable diseases, may be affected by the physical condition of the people and also, quite possibly, by climatic conditions. Writers on previous epidemics advise the public to maintain good health in order to combat disease; this is just as true today as it was a century ago. The appalling conditions following outbreaks of certain communicable diseases during the Middle Ages bear witness to this, for they continued uninterruptedly for many years and destroyed at least twenty-five per cent. of the population of Western Europe, due chiefly to the impoverished and exhausted condition of the people and the absence of official health control. At the present time, under almost the same conditions, epidemics of infectious diseases have practically devastated certain communities in various parts of the world. Not that the people of the United States have been reduced to such an unfavorable physical condition, but it is a fact that the resisting power of the people of this country has been considerably lowered by recent events. No one familiar in a practical way with the subject maintains that persons in robust health do not contract influenza or other communicable diseases, but the fact remains that those who have a good resistance stand a better chance of escaping these diseases and more particularly the unfavorable complications which frequently occur. No one doubts that this is true of tuberculosis.

At no time in the history of this country has an outbreak of infectious disease occurred under more disturbing circumstances than has the recent visitation of influenza. We had been subjected to a long period of nervous tension and depression. For the first time the people were officially requested to eat less food and to make radical changes in their diet. We had to provide an abundant supply of food for our army abroad and to make necessary contributions of food to war-devastated peoples. Such a state of affairs lasting for three or four years was certain to lower the general vitality, particularly when associated with a prolonged nervous strain. Fortunately, food restrictions were not carried to an extreme point, nor continued for a long period, but the resisting power of the public was visibly affected. An individual is not always aware when his health is below par; the public is far less observing when its vitality is reduced.

During August, 1918, a careful investigation was made in the City of New York to determine as far as possible the effect of food restriction, change in diet, nervous tension, etc., upon the public health. This test, confined to one locality, was not expected to furnish conclusive evidence, but it is reasonable to assume that pertinent and dependable information was thus obtained. Over five hundred families were visited, chiefly on the extreme east and west sides of the city—homes of the laboring and the poor classes. Outbreaks of infectious diseases usually appear first and often are propagated with great rapidity among this class of people. At the time of the investigation

the sale of unmixed white wheat flour was not permitted. Millers were required to add to white wheat flour a certain amount of other specified cereals before milling, and even this mixture could not be purchased by the public without buying at the same time an equal amount of a substitute, such as oatmeal or rice. When it is borne in mind that bread is a most important article of food, particularly in the restricted diet of the poor, the effect of this regulation is evident. The cost of the cereals used as substitutes was frequently greater than that of the wheat flour. The amount of wheat flour purchased was, therefore, necessarily restricted. The substitutes were often of a poor quality and unpalatable and little was eaten. Mothers reported that the children would not accept cereals as substitute for bread and while a certain amount was eaten by the adult members of the family, much was thrown away. Bread made with a mixture of the white wheat flour, prepared under Government order for general use, and the various substitutes was usually a failure. It was very distasteful and often could not be eaten, largely for the following reasons: The gluten in wheat has very pronounced "binding" qualities, *i.e.* its elasticity and tenacity permit expansion of the dough during "rising" without rupture of the mass. Bread made in the old way is light, porous, palatable, and healthful. Cereals have this "binding" quality to a very limited extent, and bread made with them cracks open and collapses and is soggy, unpalatable, and indigestible. Little or no relief was gained by buying bread from the baker, for he, too, was obliged to buy a certain amount of substitutes for use with wheat flour. Other foodstuffs were extremely high in price and, as a rule, enough could not be purchased by the poor to furnish sufficient nourishment. It was commonly remarked that children often left the table hungry and clamored for food between meals. The adult members of the family also experienced hunger but wished to do their patriotic duty and made no complaint. It was said that good bread was seldom found in the workingman's dinner pail. During this investigation it was often stated that children were irritable and did not sleep well. This affected the comfort and health of the parents, especially when the apartment consisted of two or three rooms, for if their rest was disturbed they were not fitted for the next day's work. It is true that during this period the laborer received increased wages, but food, clothing, etc., were correspondingly high in price and little relief was obtained.

The investigation also dealt with those who were financially able to purchase a generous supply of food at a greatly increased price. Largely from patriotic motives, however, the diet of these people was restricted in amount and radical changes were made in the character of their food. Until late in 1918, when most of the food restrictions were removed, it was practically impossible to get good white bread anywhere. Even the best hotels and restaurants could not supply it. Many people stated that their food had not been satisfactory or sustaining and that they were not up to their usual standard of health, and many had lost weight, conditions which might be expected among people on a limited and defective diet and under nervous tension for a long period. There is no doubt that the general lowered vitality had a great deal to do with the complications and dangerous sequelæ associated with the recent outbreak of influenza. The public know little about the importance of proper nourishment and our dependence upon it for the preservation of health and resistance to disease, and unfortunately they received only meager information upon this subject. The owner of a motor car will provide it with proper fuel for he knows if this is not attended to it will not render satisfactory service, but this person will probably give little or no attention to the most perfect machine in his keeping and the one which calls for the most careful feeding.

Influenza was especially prevalent in military camps throughout the country. Some persons who believe that the physical condition of the individual plays little or no part in protection against disease point to this fact as evidence that persons in good, healthy condition are as susceptible to communicable diseases as those in a run-down state of health. It was stated that soldiers in the camps were a strong and healthy group of young men; this is true only to a certain extent. The men in the camps were mainly draftees who had been expecting for some time to be called upon for service, and many had undergone a long period of nervous tension. They came from every walk of life; a large number were undernourished and were anemic and emaciated in appearance. The draft law did not relieve such persons from duty except in rare instances, holding that camp life would soon improve their physical condition. This is quite true, but they had not undergone this change when the influenza appeared at the camps. The great concentration in the camps and the inability of the medical department to isolate the sick went far to aid in the dissemination of influenza.

The preventive measures in operation during the recent outbreak of influenza are typical to a great extent of the methods usually employed in dealing with outbreaks of all diseases. It is hardly necessary to state that there is a marked difference of opinion concerning the propriety and efficiency of these measures. In minor details this is inevitable, but there are underlying principles which should govern these matters and insure a concerted and harmonious action in instituting preventive measures; for instance, some health officials believe that churches and theaters should be closed during extended outbreaks of some communicable diseases, others believe they should remain open. These disagreements are disturbing not only to the medical profession, but to the public, for it is assumed that if there is no uniformity of action there can be no well defined fundamental principles to guide us, which is not the case.

Public schools are not infrequently closed during epidemics, presumably to prevent children from coming in close contact with each other. The closing of schools is based upon theory rather than upon practical experience. This procedure in fact encourages the transmission of in-

fective agents, for it forces the children out of school where they may be kept under careful observation and they then congregate in large groups about the hallways of tenements and in other places where they are under no control or observation. Children, as well as adults, will come together in different places without regard to health regulations, particularly in poor districts where epidemics make greatest headway. Mild and unrecognized cases which constitute the most dangerous medium of infection are far more apt to be detected and dealt with promptly when brought under careful observation by competent examiners. Furthermore, the closing of public schools suspends education, sometimes for two or three months; this is a serious matter and particularly unfortunate if it is not of definite protective value. It is far better that public schools should remain open during outbreaks of infectious disease, and the children upon arriving in the morning should pass in review and be given a careful visual examination by a trained nurse or an intelligent layman whose training would require but a short time. Well marked and even mild cases and previously unrecognized cases are quite certain to be detected in this way, particularly if the teachers keep careful watch during the day. Children presenting evidence of disease should be promptly removed from school and given a physical examination. Actual and suspicious cases are thus discovered, and in addition other cases in the little patient's family and in the neighborhood are brought to light. It may be said that there is no more effective means of educating children regarding preventive measures and the preservation of health than by the method just referred to.

Other meeting places, such as churches and theaters, are often closed during outbreaks of infectious disease. Here also, it is possible to keep people under some form of effective observation and discipline, which may be of great value in public education as well as a means of prevention. We should bear in mind that people will congregate notwithstanding laws to the contrary, and if not allowed to go to the places above referred to where they are amused or benefited, they will go elsewhere. It cannot be stopped. The public should not be deprived of entertainment during an epidemic. Entertainment goes far to relieve worry and tension and it may secure better cooperation of the public with health authorities. It is true that persons suffering with infectious diseases will enter schools, churches, theaters, etc., unrecognized. If they do not go to these places, however, they will associate with other groups of people where the danger of infection is far greater than in churches and theaters where the people remain seated and to not wander about the place, thereby increasing the danger of transmitting the disease. Officers and employees of public meeting places may easily be trained to render valuable cooperation during epidemics. A casual inspection of those entering the building would quite likely detect such persons; the suspect might be questioned quietly, and if necessary, requested to leave. If this procedure was followed in all meeting places by official order, the publicity would go far to deter those who were ill from visiting these places. A few words from the pulpit or stage regarding the manner in which the disease is transmitted and how it may be prevented would also be a means of public education.

The value of disinfection of street and railway cars as well as other public vehicles has been freely discussed and various opinions diametrically opposed have been expressed as to the justification of such a measure. I believe it has not only no practical value but it is misleading to the public, for it does not indicate the real means by which infectious diseases are transmitted. Such a measure involves an enormous expense and delay to transportation companies and interferes very seriously with public travel. It may be assumed that the disinfection of public conveyances is recommended on the ground that these vehicles harbor pathogenic organisms in an active state and in condition to transmit disease. While this theory is plausible the fact is that diseases are transmitted in public conveyances in the usual way—by personal contact.

It is reported that during the recent epidemic of influenza in certain cities, the general use of face masks was ordered by the municipal authorities. The purpose of a face mask in dealing with influenza or other acute infectious diseases of the air passages is to intercept infective agents; therefore, their use in connection with the sick either in hospitals or at home may be of value as a measure of prevention. Reliable evidence to this effect has been presented; however, for general use by the public it is an impracticable and insanitary measure and should never be enforced. What supervision would a department of health have over the wearer as to the length of time the mask should be worn—when it should be removed —and when and how these articles should be sterilized? In one of the cities recently visited by influenza where masks were worn at the option of the individual, it appeared to be the practice to slip the mask down under the chin during conversation; such an abuse of the measure makes it ridiculous and useless as a means of protection, and belittles cleanliness, a most important means of prevention.

The reason why uniform preventive measures are not employed is chiefly the difference of opinion as to the means by which infectious matter is transmitted. The domination of the belief that infective agents are commonly transmitted from one person to another through the medium of clothing, baggage, money, merchandise, etc., is largely responsible for this, and until it is disposed of conflicting measures will continue to be employed in dealing with outbreaks of communicable diseases. This belief which is of ancient origin is referred to by earlier writers as the "fomites" theory. It still has many advocates among the medical profession and is very popular with the public. The theory is extremely plausible and offers a ready explanation for any outbreak of disease whose origin is unknown. It encourages carelessness and discourages painstaking investigation for the real cause of infection; it has in this way been largely responsible

for the extension of disease. I have personally investigated many statements that persons have contracted diseases in this way, but after careful and exhaustive examination have usually found that the infectious matter was conveyed in the usual way—by contact with the sick. Superficial investigation is the chief support of this theory. This statement also applies to the aerial theory of the transmission of disease, which is hardly deserving of consideration.

When maritime quarantine was instituted in Venice during the fourteenth century the fomites theory held full sway. It is authentically reported that incoming vessels were required to remain at anchor in the harbor for weeks while their cargoes were placed on deck for exposure and so-called purification. No mention is made of the detention of the passengers and crews on board or of prohibiting persons from shore from visiting the vessel. There is good reason to believe that there was free intercourse in this way, and that the true source of danger—personal contact—was thus ignored. It is no wonder that contemporaneous reports were not enthusiastic over the results of the innovation in the way of preventive measures. As late as the eighteenth century vessels from infected ports were not, in some instances, allowed to proceed to their destination but were sunk at sea by official order to prevent infection through the medium of the cargo. Even in recent times equally worthless methods were employed as a means of protection. Not many years ago, iron rails were ordered to be disinfected in certain sections of this country in order to prevent the spread of yellow fever, a disease which we now know is transmitted only by a certain variety of the mosquito. Even in the year of our Lord 1918, almost as useless requirements were imposed upon the public as a measure of protection against influenza.

Little by little, those who have worked in the field and have had long practical experience with infectious diseases, have learned that it is persons and not things which transmit disease. Success in preventive medicine depends upon knowing the true media of infection and upon the early detection and isolation of cases of infectious diseases. Every effort should be made to discover mild, ambulant, and unrecognized cases, which are the most dangerous source of infection since they commonly escape notice and are under no supervision. For a long time it was believed that the great increase in the number of cases of infectious diseases at the beginning of the school year was largely due to the transmission of infectious matter by means of the clothing of children in whose homes some form of communicable disease existed. "School corps" which were organized by departments of health to investigate details connected with the spread of disease among school children, soon presented conclusive evidence that it was not so-called infected clothing but the presence of mild and unrecognized cases in the school that was responsible for the increase of infectious diseases at the opening of school.

Some time ago, there were many second-hand clothing stores in New York City whose proprietors were engaged in a thriving business. These stores were usually on the first, or street floor of the building, the rear rooms opening into the store being the living quarters of the proprietor and his family. The various members of the family were in the store in close contact with the clothing a large part of the time. There is probably no doubt that some of the articles of clothing offered for sale belonged to persons who had died of infectious diseases. There were no health regulations at the time requiring the disinfection of such articles, yet after a long and careful investigation not the least reasonable evidence was obtained that the families of the proprietors of these places who were constantly exposed to the clothing contracted disease through this source. The same result followed the investigation of rag-picking which at that time was engaged in extensively. Rag-picking was carried on by Italians in dark and poorly ventilated cellars, sometimes under tenement houses. Whole families took an active part in the work and there were practically no regulations as to disinfection of the rags, yet there was not the slightest ground for believing that these people contracted disease in this way.

A number of years ago I investigated in Egypt the danger of infection through rags brought from there to the United States for the manufacture of paper. Egypt is constantly visited by outbreaks of infectious disease which exact a very heavy toll from the population, due largely to the poverty and ignorance of the people. At the time of the investigation, Egyptian rags were composed chiefly of the cast-off clothing of the natives whose costume consisted usually of a single garment. It need hardly be said that these garments were not discarded until they were unfit for use and were usually in a filthy condition. The rags were collected throughout the country, placed in rope crates and sent to Alexandria for sorting. This was done in badly ventilated apartments, chiefly by women and children who were in close contact with the clothing for long periods. Egypt was then practically under British rule, and the carefully prepared statistics presented no evidence that the rags were the source of infection. It was therefore concluded that if the rags did not convey disease to the rag-pickers of Alexandria, they would not be a source of danger after reaching this country, many months later.

In this connection, it may be said that a visit to the Treasury Department at Washington furnished valuable and impressive evidence concerning the fallacy of the fomites theory. Here an enormous quantity of old and dirty paper money was being handled and rehandled by a large force of employees prior to destruction. I was informed by the officers in charge that there was no evidence that clerks had been infected through this source although no disinfection had been done or other special action taken as protection. Evidence in support of the fomites theory is usually based on the most scanty information. For instance, it was recently reported in the daily papers, that a cashier in a restaurant died of scarlet fever and that he was undoubtedly infected by money which had passed through his hands. There was not the slightest proof of this, but the theory was plausible and was readily accepted.

It must be borne in mind that rag-pickers, dealers in old clothes, employees in banks, and others who are constantly handling or coming in close contact with articles alleged to be media of infection, are subject in a general way to the same exposure that others are, and there is no reason why they should not contract infectious diseases in the usual way. If the fomites theory was sound these people would be far oftener infected than others. *No such facts, however, have appeared.*

The disinfection of apartments at the termination of infectious disease was formerly held to be absolutely necessary. It was believed that pathogenic organisms in an active state were present in these rooms and that disease could be contracted by those entering the apartment. This was so generally believed that discharges of the patient were not promptly destroyed and other details of cleanliness were largely overlooked; everything was left for so-called terminal disinfection. Now we know that protection depends upon the prompt destruction of infective agents in their active state, as they come from the body of the sick. This, it will be seen, is closely associated with cleanliness. If this is carefully attended to we need fear little from the room itself. In several cities where modern preventive methods are employed with the most gratifying results, the disinfection of apartments has been practically abandoned. The great influence of fresh air upon the welfare and comfort of the patient at all times is now more fully appreciated. Until health officials recognize the imperative necessity of carrying out modern methods there can be no uniform and successful measures in preventive medicine.

The education and cooperation of the public are vitally necessary to the protection of the public health. People know comparatively little regarding the preservation of health and the prevention of disease, notwithstanding a belief to the contrary. It may be said in passing that differences of opinion among health officials and conflicting action are not likely to furnish the public with satisfactory and dependable information upon this subject. The importance of modern research in identifying specific organisms and the means of combating them cannot be overestimated; yet it is equally important that the most careful researches should be made to discover the source of infection and to observe under what conditions the individual is most susceptible and most resistant. Important discoveries in bacteriology are far ahead of their practical application so far as the education of the public is concerned.

Articles on public health frequently appear in daily newspapers and magazines, and while these may be interesting, this literature is often based upon theory, and the opinions expressed frequently differ widely on essential points upon which all should agree. This is due largely to the fact that such articles commonly do not emanate from authoritative sources. Bulletins of various kinds are issued by health departments, but these are for the most part largely technical in character, and as a rule do not go beyond the hands of physicians. Even bulletins prepared for general distribution do not reach the homes of those most in need of this information. Departments of health throughout the country, although constantly devising means for health protection, have taken no concerted action in the education of all classes of society upon the subject of the preservation of health and the prevention of disease, and little real advance has been made in this direction. The country is surfeited with health ordinances, but these cannot attain the desired result, and never will, without the aid and cooperation of the public. Many societies throughout the country render valuable aid in public health instruction, but they are local—are not allied with nor do they follow the same line of teaching as other organizations in other parts of the country; besides they reach only a small fraction of the population, whereas practical success in this field demands uniform and universal methods.

Two years ago an extended investigation was made to ascertain the views of the public, particularly of the poor and laboring classes, upon the subject of health preservation and the prevention of diseases. A thousand families probably were visited on the extreme west and east sides of the city. The investigation was made by experienced trained nurses and the information was generally obtained from the mother of the family. These people were asked to give their opinion regarding the means by which infectious diseases are transmitted and if they were willing to aid and cooperate in the protection of the public health. They were then asked also if they had received any instruction on the subject and in what way it had been presented. It would be difficult to imagine more fantastic and erroneous theories regarding the transmission of disease than those expressed during this investigation. Almost all of those interviewed expressed a genuine desire to be instructed in order that they might be able to protect their children. No one reported receiving any definite or satisfactory information upon the subject, at least not in a way that was satisfactory or effective.

The value of public education regarding the preservation of health and the prevention of disease cannot be overestimated; every class of society should be instructed in this direction. It requires but little study of this subject to appreciate that only doubtful success follows the action of a municipal health department in dealing with an outbreak of infectious disease if the public remain inactive and each citizen does not understand he must play an important part in the prevention of disease and the preservation of health; until this cooperation is gained only indifferent success will be secured in the protection of the public health.

Employers should be taught that they constitute an exceedingly important factor in obtaining this result, for the possibilities of aid in this direction are very great. Active work has already been begun in this direction. During the past year influenza invaded the coal fields of Pennsylvania and claimed many victims. At least one of the coal companies appreciated the importance of extending aid in securing the cooperation of their employees in this emergency. The method em-

ployed was as follows: Six intelligent workmen from each mine were brought together and briefly instructed regarding the cause of influenza, the means of transmission and the usual symptoms of the disease. One of these men was stationed at the mouth of each mine shaft when the miners went to work, at or before seven o'clock in the morning. If any looked ill or were found coughing or sneezing or were regarded as suspects they were requested to remain in a nearby apartment until an examination could be made by one of the staff of visiting physicians who called about 8 A. M. At each examination one or more cases of influenza were detected and the patients were sent home. Their addresses were given to the nurses on duty who soon afterwards visited them at their residences to ascertain the conditions present, and to see if they could render assistance. Frequently other members of the family were found to be ill with the disease, often with no medical assistance and no precautionary measures against further spread. In many instances the nurse took charge and rendered all possible aid. The coal company also cooperated with the local health authorities by reporting all cases which came under its observation. It may be added that a bulletin, printed in six different languages, containing in simple terms a brief statement regarding the cause of influenza, the manner in which it is transmitted, and the usual symptoms of the disease, was distributed freely among the miners and their families with very satisfactory results. These means were not only most effective in preventing the extension of disease but undoubtedly saved many lives.

This modern method of prevention by gaining the cooperation of the public through the agency of the employer and his employees came under the observation of the writer and furnished a striking illustration of the very great aid which may be gained in this way. Among other things it showed the untruthfulness of the statement that the poor or working classes show but little or no interest in the prevention of disease and the preservation of health. In this instance, keen interest was shown from the beginning by the miners in the preventive measures undertaken by their employer, and the young men selected for the visual examination of workmen at the mine shafts were not only greatly pleased by being selected for this purpose but were faithful in the performance of their duties; besides the miners expressed their approval of the selection of members of their own body for this purpose. The nurses who visited the various settlements in connection with this work received grateful acknowledgments on the part of the miners and their families concerning the aid extended by their employers. The nurses were escorted from one place to another by women and children eager for them to visit their homes, and in many ways showed their gratitude for what they had done in their behalf. The miners were manifestly pleased with the aid extended by their employers, which goes far to prove the inestimable value of welfare work among employees. If this practice could be extended, it would not only promote health and happiness among these people but would lessen the gulf between capital and labor.

Employers as well as the general public have but little or no definite instruction in this direction, therefore the full value of their aid in the prevention of disease and the preservation of health will not prove fully satisfactory until they have received proper information upon the subject. As a rule, employers are anxious to do their share, but in the absence of proper knowledge concerning the most effective means of extending aid, they are quite apt to decide for themselves what they should do. We find this in the elaborate and expensive fitting of rest rooms, toilets, and lavoratories for employees, which while they appeal to the eye, is largely an extravagance without any educational effects. It is of very little value to the employees, for they cannot maintain these conditions at home, and it teaches little or nothing so far as the maintenance of health is concerned, which would not be conveyed by modern simple and inexperienced fittings. The unnecessary amount of money which is spent in this way would go far to carry out reasonable and effective preventive measures.

In what manner public information concerning the preservation of health and the prevention of disease is to be conveyed to the public in order to fulfil its purpose is a problem which must be given the most careful and serious consideration. It may be safely said that it cannot be successfully accomplished by the multiplication of health ordinances which repel rather than attract interest and cooperation on the part of the public. It must be through agencies which reach the people directly and which have the respect and confidence of various classes of society. It is not impossible to reach every household if proper means are employed. We have learned something of this in connection with the activities of those in charge of the liberty loans.

While the aid of health authorities is most valuable in imparting this information, it is necessary that the organization in charge of the matter should be national, it should speak authoritatively and should be capable of deciding upon the best means of public education, which would be instrumental in bringing together in harmonious action all the various agencies to take part in the work. This must be done largely as a public duty and without remuneration; the important factor being the uniformity of instruction and the dissemination of information approved by a body of experienced and practical sanitarians. There is no doubt that clergymen would be ready and willing to aid in this important work. They are influential and frequently speak from the pulpit upon matters of public interest, and a few moments' instruction would be of very great value. Others who have the confidence of various societies and associations would also constitute a most important means of conveying authorized information to their hearers. It is unnecessary to speak of the value of trained nurses in disseminating knowledge concerning the preservation of public health, whenever they are available for this purpose. Moving pictures, exhibitions, bulletins, simply and properly prepared, and the like would also be of aid in this direction. It is not

difficult to understand that whatever the various agencies may be by which instruction is conveyed there must be a parent organization to direct and insure uniform measures. Under these conditions there is not the slightest doubt as to the success of a movement of this kind and its inestimable value in contributing to the health and happiness of the people.

205 West Fifty-seventh Street.

JAUNDICE.*

By MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND VISITING PHYSICIAN TO THE LENOX HILL HOSPITAL.

You may be surprised that I should speak to you tonight on a subject that is as old as medicine itself. For ever since medicine has been known jaundice with its symptom complex has been recognized and treated. But the reason I have chosen to speak on it is because of its great practical importance, and because there are new points to be applied nowadays which are helpful in the differential diagnosis.

When we have a case of jaundice, the first thing to be done is to discover its origin. With jaundice we have a condition in which the skin is impregnated with biliary pigments; it is yellow, and the sclera is yellow. The word "jaundice" derives its origin from the French word *jaune*, meaning yellow, and therefore the word means nothing but a yellow color. We find this yellow color, this jaundice, existing in different diseases which have to do principally with the gall-bladder. We all know that the liver is the organ which manufactures the bile; this organ contains a system of canals which lead ultimately through a little reservoir, the gall-bladder, into the duodenum. If for some reason or another one of these canals becomes closed and the bile cannot reach its outlet there will be a damming back of the bile and instead of going to the intestine it will find its way into the blood and from there reach the skin; from the skin it can again be eliminated by way of the circulatory system and passed through the kidneys with the urine.

Another type of jaundice occurs when the liver cells which manufacture the bile lose the power of sending the bile through the biliary canals; they are still able to manufacture the bile but are weak, cannot discharge it properly, and it goes in another direction and reaches the lymph system, and the blood system, thus producing what is known as hepatic jaundice.

There is a third type of jaundice in which it is believed that the bile is manufactured in the blood itself, the liver having nothing to do with it, or very little. But I should think that in this type—called hemolytic jaundice, in which the blood corpuscles break up easily and the blood itself is found to contain bile—the liver itself must also be in some way involved.

When we are confronted with jaundice, which is only a symptom complex, we must try to find the cause, the origin of the trouble, and make a differential diagnosis.

*An address delivered before the Academy of Medicine at Syracuse, N. Y., on April 15, 1919.

Before we go into the symptomatology, and especially the differential diagnosis of the different types of jaundice, it will be well to dwell for a few moments upon the symptoms found in jaundice. When there is trouble with the bile and it accumulates in the tissues, then we have some symptoms that are due to this accumulation, and other symptoms which are due to the original disease, and we have to combine the two to make the complete picture. The symptoms which we usually find and which are due to the bile as such are slow pulse, drowsiness, lack of mental concentration, lack of energy, and quite often an itching sensation. These are all subjective symptoms. These symptoms are accompanied by others which are due to the original disease. Many cases have no pain at all; in others, the patients suffer severe pains, chills, fever, and are very sick—seem almost dying. One can go from one extreme to the other—some being very sick, others very slightly so.

Now, as to the differential diagnosis of the different types of jaundice. First we will consider those forms which are very common, beginning with catarrhal jaundice, which is the type most frequently encountered. Here there are mild digestive disturbances, lack of appetite, nausea, perhaps vomiting, constipation. The patient has thus suffered for a few days or a week, and then all of a sudden he turns yellow, but there is no pain; then the yellow color increases, the urine becomes dark brown, and at examination bile is found. The stools are clay colored. Most of these patients never had severe attacks of pain. They come to the office and say they have been sick for only a few days, yet they are quite yellow. This is called catarrhal jaundice and it is classified as the obstructive type; that means that the duct—the bile duct or the common duct—is filled with mucus, and the bile cannot enter the duodenum; there is obstruction to the escape of the bile, and reabsorption. Some do not accept this as a satisfactory explanation, for mucus does not seem enough of an obstacle to cause the damming up of the bile. The examination of the duodenal contents, which I have frequently undertaken, shows that usually there is some bile coming into the duodenum, and ordinarily there is some mucus in the first twelve days of the disease; so that I would rather take it for granted that the mucus has something to do with the condition. Whether there is anything else behind that, it is difficult to say; perhaps there is a spasm at times—a spasm of the sphincter at the end of the common duct. Later I will cite some instances which are apt to prove that such a condition exists and gives rise to jaundice.

This catarrhal jaundice usually offers the best prognosis. All of the patients get well though in a year or two some of them may have a similar attack, and again get well.

The other group which also appears in an acute form is that where the jaundice is caused by a distinct obstruction of the canals of the biliary system, due to stones. It is characteristic of this type that there are severe pains preceding the attack, severe cramps different from the pain usually accompanying gastric affections—a pain which comes on suddenly and is very acute; in some cases it is radiating, reaching to the center and then back to

the right; but in all cases of stone, no matter where—cystic duct, common duct—there may be a slight jaundice that appears after a few days. In most of the cases in which the common duct is not involved—for instance, stones in the gall bladder alone, I think we have to deal with a spasm, and this spasm probably helps to bring on the pains; after a while the spasm is relieved, and the bile again escapes.

Sometimes we see cases of duodenal ulcer in which there are no stones at all, which have pains characteristic of gallstones and jaundice, perhaps with temperature, and yet there are no stones. Some years ago I described these cases, but tonight I will only mention one which is characteristic of the group, showing how in some instances we can reach the correct diagnosis. About ten years ago Dr. Willy Meyer operated on a patient who gave a history of very severe pains coming on every six or ten months, so severe as to require hypodermics of morphine to relieve them. He also had been treated at Carlsbad for several years for gallstones, every one believing that he had them. He came to me shortly after an attack of pain, but had no jaundice. I examined him and found that he had hypersecretion of a high degree; he complained of vomiting a great deal, and I advised him to go to the hospital for further examination. While in the hospital he became slightly jaundiced, and had a typical attack of severe pain; he also had slight elevation of temperature and vomiting. That was about the time that I began to use the duodenal bucket, with a string attached and he was one of the first upon whom I tried it. He retained it for several hours and then vomited it, but the bucket had had time to enter the duodenum, and when I examined it I found on the string a distinct mark of blood, two little streaks half an inch apart, about 23 inches from the lips, indicating that he had a duodenal ulcer. That patient had been presented by me in one of my lectures before his operation. Dr. Willy Meyer operated upon him in he Lenox Hill Hospital and found no stones at all, and the gall bladder normal, but there was a pylorospasm on account of the presence of the duodenal ulcer, which led to that continued secretion of gastric juice and at times also to a spasm of the papilla of Vater producing jaundice. In this case of duodenal ulcer without gallstones there had existed at times jaundice with fever. How does the jaundice originate in such a case or how can that be explained unless we recognize that the duodenum also for some reason or other can cause a distinct spasm in a sphincter near by or the sphincter of Oddi. This I think is a good demonstration of the existence of such a spasm and that such a spasm can cause distinct jaundice.

From the result of my experience I am inclined to assume that a mild closure, a mild spasm of that kind can exist without causing much pain. At least I think so, for the following reason: Very often if we try to obtain the duodenal contents by aspirating with the duodenal tube in the right place, we can do it for 15 or 20 minutes and yet get nothing,—no bile; only a few drops of duodenal contents, very little fluid without bile. Now sometimes it is very important to obtain the bile, so I tried again, as follows, and I did succeed. I put in warm water and let it run into the duodenum through the barrel of the syringe; then I try to lower the barrel and let the water come back by siphonage. If you do that and let the water come out, and have one syringe, and then put in another syringe and let it run out, then all of a sudden you will notice a little bile. This I think can be explained frequently by some closure of some muscle, which owing to the slight mild washing quiets down and opens up. In all of the cases that I have tried after using that method, we have almost always succeeded in getting the bile, and nice bile.

Stones in the gall bladder or its vicinity can produce such a spasm, and jaundice too.

Now if we have jaundice and have pain about the gall bladder can we make a diagnosis which will show us definitely whether there is a diseased gall bladder present or whether the stone is situated in the common duct, or in the cystic duct, or in the hepatic duct? By examination of the duodenal contents I think we can frequently gain some points which will help to differentiate these things.

If we have to deal with a diseased gall bladder, with or without stones, and decomposed bile, then we usually have a bile that is not clear and golden as it should be, but turbid; very often it looks like pea soup, dirty instead of golden yellow, and sometimes it looks greenish as though it had been stagnating somewhere. Then we certainly know that we have to deal with a diseased system about the gall blader. That is certainly the case with those patients who suffer a long time and come at a late period for their examinations. If the stone is situated in the choledochus, a good sized stone closing up that canal, then we find that bile would not be found in the duodenum while pancreatic juice would be present. I know of a patient who was operated upon not long ago in whom this state of affairs existed; he had no fever, he was jaundiced, and the duodenal contents showed no trace of bile; the pancreatic elements were absent too. Here I had to make a diagnosis of stone in the common duct; nothing entered; the pancreatic juice did not enter, bile did not enter the duodenum. He was operated upon and my diagnosis was found to be correct; he had stones in the gall bladder also. He had a big gall bladder, about the size of half a wineglass filled with big stones. You all know Courvoisier's law, that a large gall bladder speaks for malignancy, a small gall bladder for stones. I have not seen many autopsies regarding this law, but I have seen many patients at operations, and I find that there are many very big gall bladders with a stone and a good nature; they have no malignant disease. The one I referred to had that type—a big gall bladder with stones. So we cannot depend upon that rule, though the majority may be like that. It is very different whether we judge by the living or the dead body, for at autopsy we see only the end cases, whereas in life we have to deal with different conditions. I would not say in half, but I would certainly say that Courvoisier's law would not apply positively in a number of cases in making a diagnosis on the living, for I very often feel these gall bladders and they are big and yet there is no malignant disease.

We will now consider the jaundice that is of a protracted character. Here we can deal with stones

too, and we can also have some other affections which are the cause of that yellow color. Pains recurring at periods always speak for stones. Protracted jaundice, without pains at all, usually is due to that type which is termed biliary cirrhosis of the liver—big liver. There we may find not much suffering, not much pain. The patient can live quite a while and continue going about. I do not say he is not a sick man. But there is another type in which there is suffering with no distinct periods of interruption, and with it jaundice in addition; that is the malignant type. Another point of importance is that in the malignant type we may find plenty of bile in the duodenum, even clear bile. Bile in the stools, too; and not withstanding all that extreme jaundice. The reason for that is that the malignant disease starting in either the stomach and extending toward the liver, or starting in the pancreas or the gall bladder, will involve a certain field of the bile area of the liver constricting some of the canals and a certain amount of the bile has to go back, but a great deal of the bile in the healthy part of the liver which is collected will enter into the free passages. That is what happens in a great many of these cases.

In this connection I will mention a patient whom I have observed very recently. The case is interesting on account of the diagnosis. This patient did not suffer much, but he had lost quite a little weight and became extremely jaundiced. He also had some nodules in his forehead. These nodules were excised, and the pathologist reported a malignant disease. The gastric contents showed absence of hydrochloric acid, presence of blood, and lactic acid. Palpation revealed some resistance in the liver region. Examination with the duodenal bucket showed the pylorus to be free and gave no evidence of ulcer in the duodenum. The duodenal tube showed clear bile; but the pancreatic juice revealed absence of the trypsin ferment. This is often found in severe pancreatic lesions. In this case I made a diagnosis of cancer of the stomach involving the pancreas and liver. The liver could be palpated, but we had to base the diagnosis of cancer of the stomach and pancreas on the clinical findings in conjunction with the history. This patient died, and an autopsy was made, and contrary to our belief that it was a malignant disease of the stomach involving secondarily the liver and pancreas, the pathologist made a diagnosis of primary carcinoma of the pancreas. We were entitled to think that the primary place of the affection was in the stomach, for the liver is very seldom primarily affected with the cancer. . . . It is of interest to see that extreme jaundice should show plenty of bile in the duodenum, clear bile, and still a deficient pancreatic juice, and that led me to the right diagnosis in regard to the pancreas.

At present I have under my care a lady who is suffering from extreme jaundice; her color is much darker than that of a lemon, a mulatto color. She is about 70 years of age. For years she has had sugar in her urine, and besides that has had paralysis, a very severe type of the disease. She is the wife of a physician, and several surgeons have been consulted in regard to the diagnosis. I think that here we have to deal with a severe pancreatic disease which may also be the cause of the severe jaundice by pressure. I hardly think she has a malignant disease. There is no reason to believe there is a stone anywhere. She has never had pain. That is a very important point in the differentiation of these cases, with these severe forms of jaundice. The prognosis here is very grave. The surgeons don't want to touch the patient, and I don't blame them, for she would die. If she were twenty years younger, I would recommend an operation for draining the gall bladder, or making a cholecystenterostomy. What I especially want to emphasize, however, is that notwithstanding that she has so very much jaundice that I would consider it the greatest type in regard to color, she has no trace of bile in the urine. I examined the urine to-day: 3 per cent. sugar, no bile, and the stool is absolutely white, no color at all. How are we to explain this? It is quite difficult. There are two possibilities: either the liver is so diseased that there is no formation of bile or the liver has failed to send out the bile ultimately; it cannot do it; the skin is already full; it has stopped sending it out to the urine, and that is the reason why at present there is an interruption of the biliary excretion. It may come on later, but just now there is no trace of bile in the urine.

This matter of absence of bile in the urine is also found in another type of jaundice, the hemolytic type, in which we see the bile more or less formed in the blood, and there is no damming up of same in the liver, and there the urine usually contains no biliary pigments, the stool is colored, and still the patients have jaundice. In this particular type there is frequently a big spleen; and as all know, the main characteristic of this type of jaundice is that the red blood corpuscles are markedly fragile. They begin to be broken up already at 0.7 per cent. NaCl solution, while normally it begins at 0.4 per cent.

It may be well now to consider briefly the medical treatment of jaundice. In the acute forms the patient should have plenty of water, perhaps Carlsbad salts, and a light diet. That is the treatment for catarrhal jaundice. The same treatment applies in the type in which there is slight fever and jaundice, a form of jaundice which appears almost epidemically, in young persons 15, 18, or 20 years of age. They are sick for a week or two and then they are all right, and the condition does not recur. It is very similar to the catarrhal jaundice excepting that there is some temperature, usually of a mild type present. All the patients I have seen have gotten well. Here the treatment is rest in bed and light diet; the same régime as above, water, saline laxatives.

If, however, we have to deal with a patient who has stones, and is suffering with a severe attack of pain, perhaps no fever, we give hypodermics of morphine, and the next day he may be all right; he is jaundiced then for a few days; his blood is normal; no temperature. In such a case we simply keep the patient quiet, nourish him frequently with light food, and then give him bicarbonate of soda with glycerin—and he gets well. We can wait and see. If he has another attack, and if these attacks occur with frequency, then we have to be very much more careful, and we have to consider whether an opera-

tion is indicated. In these cases the *x*-ray helps very much in making a diagnosis, and an *x*-ray picture should always be taken. If stones are visible, and if the patient has had several of these attacks, I would advise operation for the removal of the stones; but if the *x*-ray shows nothing and there is no temperature and a low leucocyte count I would not advise operation; we must be guided by the condition of the patient,—the severity of the symptoms and the desire of the patient; we must combine the indications. If we have an increase of the leucocytes,—the polynuclears being increased, say 80 per cent. or so,—and we find that the duodenal contents in the fasting condition are turbid, I would have the operation performed. It all depends upon the symptoms, whether we can make the diagnosis, or there is something by which we can see that the condition is not dangerous and we can let it wait, or whether we expect something more serious to develop. If we find these anomalies, a turbid bile, increase of leucocytes, polynuclears increased, I am in favor of operation. These attacks are usually accompanied by chills and fever.

Now we will consider the subject of protracted jaundice. If we have to deal with the stone form of jaundice, after it has lasted from five to six weeks without abatement, we are entitled to make the diagnosis of a stone, in the common duct, and these cases should be operated upon, for we cannot tell how long they will go on and continue to get worse. In these cases we usually find either no bile at all in the duodenum, or it is turbid, but the recurring pains are the main indication; an attack of severe pain in which morphine is required, then relief for a time and then another attack. These patients should be operated upon.

Sometimes we may have a case of protracted jaundice without pain, and a stone may be the cause of that. I had a patient of that kind in the hospital not long ago. He had a very large liver; he had also a prolongation beneath the liver, which I thought was the gall-bladder, and in it I could feel something hard which I thought were stones. That patient had no bile in his duodenum, or almost no bile. The duodenal contents were not even straw colored, certainly not yellow, but almost like water. The pancreatic juice revealed the presence of all the ferments, and that is the reason I made the diagnosis in this particular case, that if there is a stone it must be lodged in the choledochus. I wanted that patient to be operated upon, and I think he would have been, but the administration sent him out after he had been there two weeks. I had studied everything, gotten everything ready, but the patient had no money or did not want to pay for the operation, and so he was discharged. That was about two weeks ago. In this particular case the diagnosis was really very difficult; still many symptoms were lacking to make a complete picture of a malignant disease, and that is why I still think that this case was probably due to stone and not to malignancy. Suppose we are in doubt? In such a case operation is demanded. This patient was about 40 or 44 years of age, a man in good condition, who could well stand an operation, and he should have the benefit of the doubt. Suppose he has a cancer? Then he is opened, and in such a case where there is no bile in the duodenum, an operation could be performed to make him more comfortable; the gall-bladder could be attached to the stomach or intestine so that the bile could flow out there; but if it was really due to stones he could get entirely well. Such patients should always have the benefit of the doubt. This particular patient may still turn up some day, and we may arrange to operate yet.

In biliary cirrhosis of the liver the prognosis is not very good. An operation cannot accomplish very much, for there is occlusion of the ducts within the liver and we have to deal with partial contraction of the little canals; but even in such cases we should not give up hope. Not long ago I had such a patient; he had an enlarged liver, was jaundiced and the abdomen was filled with ascites. He had also water in his feet, and could hardly walk. He had been to a renowned surgical clinic and was told that the condition is probably malignant and that an operation could be performed but without much benefit, and that he would die any way. So he was not operated upon. He came to me while I was in the country, with his physician. I examined him and found that state of affairs, and I told his physician that I could not then decide whether or not it was a malignant condition; it might be a biliary condition, one of hypertrophic cirrhosis of the liver, pure and simple and that an operation would not do much good. He came then to the hospital in New York, and waited for me to return. When I came back I found him there in a very bad condition. I was afraid that I might omit some chance in the way of surgery, and did not want to have that on my conscience, so I had some one else in to see him, but this surgeon agreed that he could not do anything. Then I gave the patient small doses of calomel followed by iodides and he began to improve. (A Wassermann test had been made and the reaction was negative.) The man continued to improve; he lost some of the fluid from the abdomen without tapping, his feet grew slim, and he was able to return to his home in Dayton, Ohio, where he continued the regimen I arranged for him. There was some achylia in his case, but he had no cancer symptoms that I could make out; so I gave him a liberal diet and told him to take calomel every second week. He continued to improve, lost all his symptoms, and came back looking well, without a trace of jaundice or ascites, and feeling like any one else. Such a case shows that sometimes we may be mistaken in our conclusions regarding malignancy. We thought he had biliary cirrhosis of the liver which was probably the correct diagnosis. I don't say that a similar treatment would succeed in all these cases, but in some we do succeed, and it is necessary for the physician to try everything and not to give up, especially where nothing can be done surgically.

In the hemolytic type of jaundice there is an enlargement of the spleen present, and a great many surgeons have tried to cure it by cutting out the spleen,—by splenectomy. Personally I have not had much experience with that, but I certainly would recommend such a procedure when it seemed required,—in that form of biliary cirrhosis with big spleen. I had two jaundice patients of that sort—big spleen, big liver. One of these was to be

operated upon, the other did not want an operation. I tried to influence the spleen and liver by radium treatment, and for quite a while radium was applied to both patients One of them improved considerably and was able to leave the hospital and go home. The other died.

I have said nothing of jaundice in infectious diseases, septicemia, etc., but have confined my remarks to those conditions which are more commonly met with.

20 East Sixty-third Street.

A STUDY OF THE ETIOLOGY AND PROPHYLAXIS OF RELAPSE IN MORPHINISM.

By C. B. PEARSON, M.D.,

CATONSVILLE, MD.

Relapse is the great bugbear, and the source of much disappointment and vexation to those who treat or care for the addict. Usually the whole responsibility is shifted to the patient, but I look upon relapse as one of the characteristic features of morphinism, a feature that calls for careful study if we would reduce the percentage of relapses to the minimum.

So far as I have been able to do so I have searched for the cause of every relapse that has come under my observation. For the sake of convenience we will study the causes of relapse under five heads: (1) Misconceptions of the pathology of morphinism, which naturally result in wrong methods of treatment. (2) Misconceptions of the addict himself, which lead to wrong systems of management. (3) Misconceptions concerning the convalescence of morphinism, and the nature of the repair processes that nature attempts to make, which result in faulty advice to the addict and his friends. (4) Certain factors in the make-up and environment of the addict himself. (5) Perverse and foolish conduct upon the part of the addict himself or of his friends and associates.

As in many other diseases, there is still much to be learned about the pathology of morphinism. As indicated by the title, this article is not concerned with an extended study of the pathology of morphinism, but a brief survey is needed for a proper understanding of the causation and prevention of relapse.

By many morphinism is thought to be a toxemia. This is true, but it does not go far enough. However, one who does not recognize this condition of toxemia in morphinism would be likely to fail in a very important part of the therapeusis of this disease.

Others look upon morphinism as being chiefly a neurosis. They regard the addict as being of the neurotic type. Morphinism is most surely a neurosis. The persistent contraction of the pupil, the decreased peristalsis of the bowel, the subesthesia of the skin, or, in rare cases, the opposite condition of hyperesthesia, the loss of sexual desire, which is no doubt due partly at least to the subesthesia of the nerve endings about the genitalia, all point to the fact that morphinism is a neurosis. The point to remember is that these and other nervous symptoms are only a part of the manifestations seen in this disease.

The word morphiomaniac would indicate that there are others who look upon morphinism as a psychosis. There are many psychic symptoms that are both characteristic and persistent. The psychic changes are only a part of the pathology of this disease. It is a psychosis, a neurosis, a toxemia, and in my opinion a number of other things besides.

It is probable that morphine affects adversely various glands of the body; to what extent and in what manner remains to be learned. It is likely that the metabolism of the body is interfered with in this way. We know that the functions of the testicles and the ovaries are interfered with to a very great extent, in many cases amounting to a complete cessation of function. It is more than probable that the action of many other glands of the body is lessened or perverted.

The nutrition of the body is always below par in advanced cases of morphinism. As a general proposition morphine is a great anti-fat. Nearly all cases lose in weight; a few gain in weight, but even in these cases there is malnutrition. There is something wrong about the feel of the flesh in morphine obesity that is very noticeable upon palpation. I think it more than likely that there is a real abnormality about the adipose tissue in these cases.

There is an astonishing change in the appearance of the features in any case of advanced morphinism that passes from morphine narcosis to total abstinence. There is a change not only in the expression of the features, but there is a change in the contour of the face. That is, the thickness of the flesh over the bones changes. This change, however, is not uniform over all parts of the face, hence the great change in contour.

I treated a lady, who had taken morphine 25 years. She had worn a set of false teeth with comfort for many years. As soon as I succeeded in getting her off the drug her teeth were no longer adapted to the changed contour of the mouth. As a matter of fact, to a greater or less extent the contour of the whole body changes. The change is more noticeable in those who carry a good bit of flesh. I treated a fleshy lady who had been an addict for eighteen years. When she came to me for treatment, if she extended the arm the flesh would sag from the shoulder to the elbow. Upon giving the pendent portion of the flesh a little cuff, it would swing back and forth like a hammock. By the time I had this patient down to gr. 1/20 4 times per day, the flesh of the arm became firm and also assumed the normal contour. I mention these matters to convince the reader that the changes that take place, while they may be only functional, are very profound. Morphinism is accompanied by greater changes in metabolism and in nutrition than any other functional disease I know. The changes in nutrition equal those seen in many wasting diseases like diabetes, nephritis, or even tuberculosis.

I am writing this for both the normal physician and the one who has the misfortune to be an addict.

To the normal physician who attempts the treatment of morphinism I say that any physician who thinks that morphinism is only a toxemia, or only a mania, or only a neurosis, or only a sort of a neurasthenia, or a trifling psychosis, will find that his efforts will most certainly be followed by a prodigious number of relapses.

To the physician who is an addict, if he is deceiving himself with the idea that morphine is not very harmful in his case or that it is even beneficial, I would say that the more thoroughly he deceives himself in this respect the less the chances are that he will ever become free from the drug. The successful treatment of morphinism depends in about equal measure upon the efforts of the physician and those of the patient.

On the other hand, the more thoroughly the patient appreciates his deplorable condition, the more intense his desire to get well becomes.

A conception of the pathology of morphinism that fails to take into account the profound and deep-seated nature of the pathological changes will most likely lead to perfunctory methods of treatment. Hence I say that misconceptions of the pathology of morphinism are by far the most prolific cause of relapse that we have to-day.

Next in importance as a cause of relapse are misconceptions as to the addict himself. Of course the psychology of morphinism means to a large extent a knowledge of the addict himself. And the psychology is a part of the pathology of this disease. What I mean in this connection is what the ordinary observer learns about the addict from long association with him and his kind. That is, all the little mannerisms, peculiar beliefs, mental attitudes, moral torts, and habits of thought, likes and dislikes, and lastly the addict's peculiar point of view regarding himself, the drug, and others who are afflicted with the disease, etc.

A lack of this technical knowledge leaves the physician all at sea as regards the management and control of the addict. I depend altogether upon this knowledge of the addict and his devious ways to control him. I never under any circumstances use any form of restraint. Nothing so commands the respect and confidence of the addict as the thought that his physician knows how he thinks and feels better than he does himself. A lack of this practical knowledge will most likely cause the physician to get the addict's ill will in spite of the best of intentions. If you lose the patient's good will you might as well discontinue treatment. The morphine addict is very sensitive about certain things. What these sensitive points are should be known in advance.

The convalescence of morphinism differs from that of other diseases in that there must be a recuperation from a peculiar mental condition, from a peculiarly exhausted nervous condition, together with a recuperation from a characteristic malnutrition of the whole body.

Morphine seems partially to paralyse the motor nerves, apparently making it necessary for the brain to send out greater and stronger motor impulses, as the addict becomes more deeply involved in his addiction. On the other hand, the need for the inhibitory impulse becomes progressively less. At least I judge that this is the case from what we see when the drug is too quickly withdrawn. The heart beat becomes rapid and irregular. The bowels that, while taking the drug, were in a condition of semiparalysis, become exceedingly active, resulting in cramps, diarrhea, tenesmus, and pain. We also get cramps in the legs and arms. In fact, the whole body seems to be working like an engine with the governor belt thrown off. The sexual powers that have lain dormant for years manifest an extreme activity resulting in eroticism and frequent involuntary emissions of semen in men, and often in nymphomania in women and in profuse menstruation in those who have not menstruated in years. I do not believe in removing the drug in such a way as to bring on these extreme symptoms.

Where the drug is rapidly removed, the mental machinery is as violently disturbed as the physical mechanism. Even when the drug is removed slowly and cautiously, there is a lack of emotional control and a lack of mental inhibition. As to inhibition as regards speech, an elderly lady said, towards the latter part of the reduction, "I was a good Methodist when I came here but I don't know what the devil I will be before I leave."

Even when the reduction is managed slowly and carefully, that is, in from 35 to 70 days, according to the severity of the case, nature does not have quite time enough to adjust herself completely to the change. Towards the close of the reduction the patients laugh or cry with but little provocation in either case.

Another clinical indication of this lack of balance in the motor and inhibitory impulses when the drug is rapidly removed, is seen in the lack of balance in the contraction of those muscles that have to do with maintaining any particular posture. As everyone knows, no one can maintain the erect posture unless the opposing muscles are each contracted so as to balance one another. To maintain any posture with ease the balance should be perfect. When the drug is at once withdrawn nature's power of adjustment is so far lost that the patient cannot stand, sit, or lie at ease. This is perhaps the most distressing feature of rapid withdrawal.

Reduction should never be pushed so rapidly as to bring on these symptoms. Mental depression and restlessness occur long before the above symptoms appear, and serve as a warning not to stop the reduction but to change to a slower rate. Pain and discomfort, especially when long continued, are a severe strain upon both the body and mind. This is just as true in the treatment of morphinism as it is in any other condition. The more of this the patient has to endure during treatment the worse his condition is at the end and the more likely he is to relapse. The patient, after absolute withdrawal, is always in bad condition. This makes the convalescence more trying, much slower, more difficult, and more dangerous as regards relapse.

This many will not admit to be true. But as morphinism becomes better understood they will be compelled to admit this fact. Many do not believe that the drug can be taken away from the addict by the reduction process, without long drawn out stress and suffering. I say that the reduction can be managed without serious discomfort to the patient. I say further that any physician can learn to manage the reduction with comfort and safety to the patient if he will take the trouble to learn how. This may seem unbelievable to many to-day, but the time is coming when all will learn that this is the truth.

I do not say that reduction can be managed with absolute comfort. No invalid can be comfortable in all respects. The addict is an invalid before

reduction, during reduction, and until convalescence has become complete. However, I do say, and my daily experience proves it, that the addict need be no more uncomfortable during reduction than he was while taking the drug *ad libitum*.

No doctor need think that he can manage the reduction with comfort to his patient by the simple process of stringing it out over a long period of time. The time given to the reduction can neither be unduly abridged nor extended without causing extreme discomfort to the patient. The correct management of the reduction is a difficult thing to learn. It must be learned, however, if we wish to cut off a large percentage of relapses. The only way rapid methods of withdrawal can be made successful is to follow the withdrawal by a prolonged period of strict surveillance. This means a useless expenditure of time and further does nothing to build up the convalescent's self-confidence and self-reliance. To my mind this is more important as regards the prevention of relapse, than prolonged surveillance. The reason that these restraints are needed after rapid withdrawal and not during a correctly managed reduction is because the discomfort is so much greater and the mind so much more unstable.

The peculiar emotional condition of the addict during the first few weeks off the drug calls for very careful advice to the patient and to his family physician. It is a time of great danger to the addict during both the latter part of the reduction and the first part of the convalescence. I have seen patients weep at anything at all sentimental in a motion picture. It need hardly be said that all stress of any kind upon the emotions should be avoided.

The emotions that center about sex matters are among the most violent that the human being ever experiences. During this period violent attachments are likely to be made for those of the opposite sex.

It is the part of wisdom for any man under treatment for morphinism to confine his remarks to the female sex to "good morning" or other brief form of greeting during the latter part of his treatment or during convalescence. It is also a matter of prudence in other ways besides reducing the danger of relapse. For one might contract a violent attachment for one of the opposite sex who would not make a suitable companion in any way whatever. Were the addict in his usual mental condition he would perceive this fact. I do not mean that the addict is crazy during convalescence but that his emotions are difficult to control. Therefore it is the part of wisdom for the convalescent to avoid everything that might excite the emotions. Of course these remarks apply to women under treatment as well as to men.

To return again to the disturbance of the motor and inhibitory balance, which we find to a slight degree during the reduction and during convalescence as compared to the violent disturbance as seen in absolute withdrawal, I must say that, even if it be slight, it is a matter that calls for careful study. For during this condition of affairs fatigue comes on very easily. Further, extreme fatigue increases to a marked degree the lack of balance between the motor and inhibitory impulses. And there comes that difficulty of assuming any posture of ease before mentioned. These symptoms are very distressing, and unless the addict has been very carefully instructed and cautioned in regard to this matter he is likely to become at once panicstricken and resort to the drug. A hot bath followed by a few hours in bed and a prolonged period of rest afterwards will set matters right.

A frequent misconception of convalescence consists in the idea that improvement is very rapid. There are two things about the convalescence that make such a misconception at least plausible. One of these is the rapid gain in appearance and usually in flesh; the other is the wonderful improvement in the patient's spirits. The last is so marked as to deceive the convalescent himself. Ask him how he is feeling and he will at once say "never better in my life." He is perfectly honest in saying this. The fact is that no man can take morphine for 10 or 20 or more years and remember anything at all about how he felt before becoming an addict. So in saying that he never felt better in his life he is really comparing his present condition with his condition during the years of his addiction. The proof that I have the right idea consists in the fact that after the convalescent has pronounced himself never better in his life he continues to gain week after week and month after month, providing he remains free from the drug and escapes serious illness or accident.

Rightly understood, this is a tragic illustration of the seriousness of morphinism. It is always well for the convalescent and his physician to remember that the convalescent is never as strong as he looks to be.

Another frequent misconception connected with the convalescence is the supposed part played by the will. The convalescent is advised to use his will power. The convalescent himself usually thinks that this is a good idea. Nothing could be further from the truth. When I have a patient leave me with absolute confidence in his will power I expect him back again. Discretion and common sense are what is needed. The will, like the emotions, should not be put to any strain. Let the convalescent pursue the right course and he will have but little need for his will power. What I mean by this is that if the right course is pursued there will be no temptation to take the drug and consequently no work for the will to perform.

Let the convalescent get himself into a situation where there is a strong temptation to take the drug, the will power will be found to be useless. Of course the reader may say that my argument is weak because will power is needed to pursue a line of conduct that will leave the convalescent free from temptation to use the drug. I do not think so. The right line of conduct is as easy to pursue as any other, and it seems to me that the pursuit of it is a matter of common sense and discretion rather than a matter of will power. The convalescent's will is weak, I grant that, but it will do well enough for the matter in hand if no load is put upon it.

When a person with a strong will becomes an addict (and, by the way, many such characters do become addicts, contrary to the general supposition), his strong will becomes a perverted will and a decided obstacle to success. Especially is this

the case, if, along with that precious strong will of his, he is endowed with unbounded self-conceit; and the two are more often joined together than otherwise. In this case we have a patient who can be neither guided nor taught. Such a patient is very difficult to cure permanently.

Another thing that has a great bearing upon the convalescence of morphinism, in the pathology of this disease, is the fact that in the case of the addict sleep is always poor in quality and very often in quantity. The addict is prone to retire very late at night, in extreme cases not till the next morning. If he has work to do this abridges the quantity of sleep. But even if he gets the right number of hours there is but little refreshment in it. So when at last the drug is withdrawn, the addict is in an exhausted condition. Morphine enables one to draw upon his reserve bank account of nervous energy. The normal person cannot do this except under great stimulus; it is like fighting a fire all night after a hard day's work. So when at last the false stimulant is gone, the addict has not much push left, and he is in no shape to attempt any physical or mental strain.

Now as to the use of hypnotics during convalescence, it is not best for the patient to become anxious about the hours of sleep, for if he gets one hour of natural it is better than a number of hours of drugged sleep. There are only two drugs (neither one is thought to be an hypnotic) that I know of that can be used safely as sleep producers. One is a small dose of pilocarpine at bedtime and the other is small doses of apomorphine (gr. 1/120 to gr. 1/40) every four hours. Chloral, paraldehyde, medinal, veronal, sulphonal, trional, etc., are worse than useless, for they predispose to relapse; they are, indeed, every whit as effective as a cause of relapse as whiskey.

On account of the prolonged interference with both the quality and quantity of sleep the convalescent has no reserve bank account of reserve nervous force to draw upon.

There are, however, two other factors of the pathology that bring about much the same condition, and this is the fact that all the cells of the body, in addition to being fatigued, are both partially starved and poisoned. Starved because of the interference with the appetite and with metabolism. Poisoned both by the direct effect of the drug and by the retained toxins, that accumulate because excretion and elimination are interfered with.

This gives us a clear-cut idea of the physical therapeutic needs. A thorough building-up process is needed. The convalescent must digest many a good meal, must enjoy many nights of normal sleep, before his exhausted bank account of reserve nervous force is restored.

Fresh air both day and night is as beneficial in the convalescence of morphinism as in tuberculosis.

Having pointed out the clear indications, I need say no more as to the building-up process. Each physician can make use of such means as seem good to him. Drugs have but little place in this building-up process; they can do but little good at best. It is psychologically far better for the convalescent to learn that rest and out-door recreation is all that is needed.

It is especially needful that the convalescent should learn to do without all drugs, for it is about the only way to acquire a normal and wholesome mental attitude. Even though a certain line of medication may seem to be indicated, the indication for no drugs is so much more pronounced that it is best to pass up all drug medication.

The indications for the psychological management of convalescence are equally clear-cut and certain. As I have already said, there is a lack of emotional control. The convalescent becomes very romantic; he reads and quotes poetry and sometimes writes it; he becomes very gallant; he sings, or tries to do so.

While he is more alert mentally than when taking the drug, the mind skips from one thing to another. The mind is easily exhausted. The grass looks greener, the sun shines brighter; the convalescent feels so good that he is sometimes impelled to celebrate by getting drunk. Here again let me say a building-up process is needed. Whiskey and the hypnotics tear down faster than nature can build up. The simple life in the most rigid meaning of the term is what is needed. It is best to put aside for a season everything that excites the emotions, like poetry, the drama, religion, and music of a sentimental character; and especially to avoid all entangling alliances with the opposite sex.

Quiet and rest are needed for body and mind. Many patients say that they cannot rest. Every practitioner knows that, when an active person has to be subjected to weight and pulley extension in bed, the first week is very trying, the second week is less so, and after a time the most restless person becomes reconciled. It is thus with the convalescent. If he rests the first week it will be easier to do so the second week, and finally he will reach a condition of mental and physical repose. This is very essential to final recovery. When the convalescent is in this favorable condition, the building-up process goes on very rapidly.

As regards any patient's final recovery a great deal depends upon what manner of man or woman the patient was before becoming an addict.

The successful business or professional man, the skilled mechanic or farmer have many times better prospects of final recovery than the more fickle and useless members of society. The same rule holds good with women. The thorough-going housewife, the competent stenographer, typist, saleswoman, school teacher are good prospects as regards ultimate recovery. The well-disciplined farmer's wife, no matter how long she has taken the drug, makes an ideal patient as regards danger of relapse.

Those members of society who feel the constant need of amusement, excitement, entertainment, etc., make exceedingly perplexing cases to manage. I have a feeling of pity bordering upon contempt for this class of people. Those who derive their enjoyment from worthy tasks well done are easy to guide through the perplexities of convalescence. The chief difficulty is in keeping them from going to work too soon.

I hardly need say that a good environment means a great deal as regards final success. A bad environment seriously complicates things. The practical thing is, can the environment be improved? If the chief part of the environment consists in bad associates, they can be discarded. But if one in making

a living is necessarily thrown into bad company, the outlook is bad indeed. The proper thing in this case is a change of occupation. This is one of the reasons why those of the underworld are so difficult to cure permanently.

Lastly, let us consider the relation of foolish or perverse conduct on the part of the convalescent and his friends. Many patients tell me at the close of the treatment, when I advise a long rest, that they lack the time. They must at once look after their affairs. This sounds plausible. Upon close analysis it will be found that there is nothing in it. The addict's time during the first part of the convalescence is not very valuable at best. If he proposes to use this time in doing things that I have expressly advised him not to do, he will find that his time is not only worthless but that it is many times worse than useless, for he will only get himself into a whole lot of trouble and sorrow. That is, he will get back into morphine taking again. Then he will have to spend more time and more money to get free again. Some convalescents seem to have this insane and senseless mental attitude—"If I cannot drink all the whiskey I wish to drink, if I cannot associate with any class of women I choose to associate with, and if I cannot do exactly as I please without getting back into dope, then back into dope it is." Here is your strong will, reader, with a fool behind it. A strong will, unless guided by discretion and common sense, is much worse than useless.

I advise a convalescent to take his auto, camping outfit, cooking utensils, and start out for a prolonged cross-country trip alone. And I further advise him to give at least three months to this trip, assuring him that, if he will do this, he will most likely never need morphine again. He answers, "I cannot do that." I ask why not. He says, "there is no excitement in doing a thing like that." "Of course there is no excitement in it; have I not told you repeatedly that excitement is the very thing that the convalescent should avoid?" If this fellow could take along with him another bum and a couple of women of easy virtue, a complete stock of whiskey, wine, and beer, the thing might appeal to him. I admit that there might be some excitement in it, but the excitement would all end in less than ten days with a dull, heavy thud. His aching head, his tangled nerves, his rebellious stomach, would call loudly for a stiff hypodermic of morphine. Indeed, "what fools we mortals be."

To another I recommend a prolonged sea voyage. He replies, "Oh, there is nothing to see, nothing to do." "Of course not, that is precisely why I recommend it. Nothing to see and nothing to do by the end of a month will bring about in your case a condition of mental and physical repose. Just the thing you need to help you to reach complete convalescence." "A whole month, doctor? Why, a whole month of such monotony would kill me." Poor thing.

One can rest with but little expense, if he chooses to do so. However, there are many who do not think that they can rest unless they can do it in proper style. The reader may suppose that I have in mind those who are wealthy. Not at all. There are many who feel that their social status would be utterly ruined unless they rested in proper style, who are not worth thirty cents, and who can neither rest in style or do anything else in style except on credit or borrowed money.

What the American people, and most other peoples for that matter, lack is proper training and discipline.

The class of addicts that I have just been writing about are a very discouraging class to treat. Nevertheless, the constant repetition of such sentiments as the above will often bear good fruit, even with this almost hopeless class of addicts.

Fortunately addicts of this class are in the minority. As in the population at large, there are all sorts and types to be found among them.

When the addict returns home after treatment he is easily irritated. Those nearest and dearest to him should bear this fact in mind. They should be very economical in giving advice. Above all things, they should not keep him under constant surveillance. This sort of thing will drive any convalescent almost to distraction. He needs to be alone at times to give his jaded nerves a rest. The constant chattering of one's friends is wearing to the robust. They should not drag him from one entertainment to another in order to keep him amused. Constant entertainment will wear the nerves to a feather edge as quickly as overwork, worry, or dissipation.

Morphinism that has lasted for ten or more years means abridged sleep and abnormal sleep for just that period of time. It means a prolonged starving of every cell in the body. It means the partial poisoning of every cell in the body for ten or more years. It means, in the very nature of things, that there can be no short and easy road to complete convalescence.

A COURSE IN MEDICAL DIETETICS.

By L. BAUMANN, M.D.,

IOWA CITY.

ASSISTANT PROFESSOR AND DIRECTOR OF THE CHEMICAL LABORATORY, DEPARTMENT OF INTERNAL MEDICINE, STATE UNIVERSITY OF IOWA.

About three years ago, Professor Ruth A. Wardall and Miss Margaret Sawyer of the home economics department and the writer planned a course in medical dietetics for graduate students in home economics. The prime object of the instruction was to train students to qualify as assistants to investigators and specialists in the diseases of metabolism, gastrointestinal diseases and other conditions in which diet plays an important rôle.

As there is reason to believe that our educational experiment has been successful, a brief account of the course may interest the readers of this journal.

In addition to the food work given in the home economics department, the students were required to have an elementary knowledge of inorganic, organic, food, and physiological chemistry. The duration of the course was at least one academic year. The instruction was divided into three periods: First a period in the chemical laboratory of the university hospital, during which instruction was given in analytical and microscopic work on the blood, urine, gastric contents and feces. This was designed to enable the stu-

dent to note the effect of diet on the digestion and metabolism of the patient. The second period consisted of dietetic instruction in the food laboratory of the metabolism ward. Here accuracy of measurement and care in the preparation of meals were prime considerations, as the food was administered to patients who were the subjects of dietetic investigation. The wishes of the patient were consulted and the dishes were prepared as attractively as possible. The daily intake of the food constituents was carefully computed during this part of the work. During the final period instruction was given in the preparation of special diets for patients in the private rooms and wards of the hospital. These included among others, the Lenhartz diet for gastric ulcer, the Schmidt diet for studying the functions of the intestine, low protein and salt diets for nephritic cases as well as high calorie diets and those for diabetics.

In addition one lecture each week on abnormal metabolic processes and dietetic therapy was given by the writer. This was supplemented by ward walks and discussions of typical medical histories and bedside notes. This instruction afforded an opportunity to the students to observe the effect of diet on the symptoms and conditions of the patients. They also obtained some knowledge of the medical terms and method of approaching the sick.

The students appeared to be intensely interested in the work. They soon realized that too little is known with regard to the relation of diet to abnormal conditions and appreciated the need for further investigation along these lines.

The recognition of the importance of the rôle of diet in diseases of the stomach, intestines, kidneys, heart, in diabetes, gout, typhoid fever, tuberculosis, and infant feeding has created a demand for such specially trained women. One of her most important functions is to teach the patient or those concerned with his welfare the details of preparation and computation of the diet which has been recommended by the physician. It appears to the writer that once the physician realizes the advantages of cooperation such a dietitian may well become a necessary member of his staff both in private and hospital practice.

A CASE OF TRUE MEDIASTINAL EMPHYSEMA.

By GUSTAV F. BOEHME, Jr., M.D.,

NEW YORK.

CONSULTING NEUROLOGIST, POLICE DEPARTMENT OF NEW YORK CITY; PSYCHIATRIST, EDUCATIONAL CLINIC, COLLEGE CITY OF NEW YORK; ASSISTANT, NEW YORK NEUROLOGICAL INSTITUTE, ETC.

Mediastinal emphysema is of comparatively rare occurrence, and the report of a case is deemed of sufficient interest to warrant publication.

The process in the true form usually is due to the admission of air into the mediastinum from a rupture of lung tissue about the hilus of the lung or one of the smaller bronchi. It may also be caused by the rupture of a lung abscess, a tuberculous cavity, or a softening tumor. Occasionally, injury to the trachea or larger bronchi may be a cause. The air in this way escapes into the mediastinal tissues and works its way into the neck and spreads laterally and downward and upward under the skin of the neck and thorax.

It must be sharply defined from false mediastinal emphysema (subfascial emphysema), in which the air, usually as the result of pneumothorax therapy, finds its way "between the intrathoracal fascia lining the intercostal muscles and the ribs on the one side and the costal pleura on the other" ("Monographic Medicine"), and diffuses into the loose endothoracic fascia. The air remains behind the ribs and does not spread to the neck or the skin.

F. H., aged 18 months, a normal child, born normally, on Oct. 17, 1918, fell ill with a double basal pneumonia. The course was characteristic; crisis occurred on the ninth day and the child was progressing satisfactorily when, on the twelfth day of the disease, it was seized with a violent spell of coughing in the presence of the writer. In ten minutes, the coughing being quite severe (there was no hemoptysis or true pus expectorated), a small crepitant lump appeared in the suprasternal notch. The percussion note over the mediastinum was high pitched and tympanitic. In six hours the emphysema had spread up the neck to the lower border of the mandible and downward laterally over the chest wall to the eighth ribs, and back to below the angle of the scapula. Sedatives were administered, the child was kept absolutely at rest, and the nasal mucosa was desensitized with a weak cocaine solution. The child was seen with Dr. E. Hoenig the next day. For four days the emphysematous area varied with the amount of coughing, and then gradually was absorbed, the child coming to a perfect recovery. An *x*-ray taken after recovery showed no evidences of pulmonary abscess or cavity.

The writer was led to believe this was a true case of mediastinal emphysema, caused probably by the rupture of a small bronchus in a part of its lumen. He is led to this opinion by the fact that the air appeared so quickly in the suprasternal notch, because of its rapid spread, and because of the variability of the amount of the emphysema depending upon the amount of the coughing. It would seem that the bellowslike action of the lungs forced air with each expiration through the ruptured bronchus into the mediastinum. Bronchoscopy might have cleared up the difficulty, but as the child was progressing quite favorably, and the strain of the influenza epidemic was upon us, it was not undertaken.

220 Audubon Avenue.

Rabies Despite Prophylactic Treatment.—Lesieuer, Lhermite, and Jacquet report a case of rabies supervening 22 days after a bite despite intervening Pasteur treatment. Clinically the type was bulbar. The patient exhibited fear states, hallucinations, and convulsions. He was in the prodromal stage extremely emotional with sudden terrors. The affective element was markedly exaggerated. Death occurred in 36 hours with ascending paralysis. At autopsy the bulbar centers, while showing no actual inflammation, presented the changes which are most commonly encountered in toxi-infectious conditions. A rabbit inoculated with the marrow died at the end of 16 days.—*Gazette des hôpitaux.*

Colorimetric Methods for the Determination of Nitrogen in the Urine and Blood.—Salvesen has investigated the Folin-Denis methods for the determination of total nitrogen, ammonia, and urea in the urine and the nonprotein nitrogen in the blood. His results show that the methods are entirely trustworthy and give very prompt findings and are adapted to small laboratories. For the determination of ammonia and urea in the urine they take precedence over all others.—*Norsk Magazin for Laegevidenskaben.*

Medical and Surgical Lessons of the War.

WAR INDUSTRIAL DISEASES.

By ALICE HAMILTON, M.D.,

CHICAGO, ILL.,

OF THE BUREAU OF LABOR STATISTICS, WASHINGTON, D. C.

THE outbreak of the great war in 1914 found the United States equipped with many nitroglycerine plants, a full sufficiency of gun powder factories, one plant making TNT on a rather small scale and a few plants making nitro cotton and smokeless powder. At once the demand began to come from Europe for explosives of many kinds. The French wanted picric acid, the British wanted mixed powders (nitroglycerine, gun cotton powders, such as cordite), and both the British and the Russians wanted shell loaded with TNT. Factories began to spring up, especially for the making of phenol and the nitration of phenol to picric acid—trinitrophenol. This last procedure is easy and does not require an expensive equipment, consequently small picric acid plants were started up all along the Atlantic coast and picric was produced by the most primitive and reckless methods. The manufacture of TNT is complicated and few companies undertook it, but the loading of shell is simpler, and here too the work was undertaken more or less recklessly. By April, 1916, when the Government sent me on my first tour of inspection, there were already between forty and fifty plants manufacturing or handling explosives, and in forty-one of them I found some 30,000 persons employed in work which brought them in contact with some industrial poison. This does not include the manufacture of ordinary gun powder, for there are no poisons involved in that.

The substances that may give rise to intoxications of more or less serious character in the explosives industry are inorganic compounds, the nature of which was pretty well known at that time, and organic compounds which were new even to German and British pathologists and were quite unknown in America. The most important of the former is nitric acid, which in the form of mixed acid is used in all nitration processes, and all of the explosives except gun powder are nitrated bodies. Sulphuric acid is added to the nitric to take up the water liberated in the reaction which otherwise would dilute the nitric acid. At the time the war broke out we were not making nitric acid to any great extent, and therefore factories had to be built for this manufacture, and also to recover and refortify waste acid. The acid used for the higher nitrations is 100 per cent. and is excessively hard to control, for it eats through almost any substance, and leaks are of common occurrence.

The most important organic compounds used are benzene, which is the starting point for our usual method of phenol manufacture, toluene which is nitrated for trinitrotoluene, or TNT, and anilin which is first methylated and then nitrated to tetranitromethylanilin or tetryl, a powerful detonator. Fulminate of mercury is the highly sensitive substance used in percussion caps. It is made by the action of alcohol on mercuric nitrate.

In that first survey I discovered some 2400 cases of industrial poisoning among men and women employed in the manufacture or loading of explosives and I was fully aware that these were not nearly all, for it was impossible to get anything like accurate figures. Many cases were never recognized, coming as they did into the hands of physicians who knew nothing about the poisons to which they had been exposed. Many more were treated by company doctors or insurance doctors who were unwilling to give information which might seem to discredit the company that employed them. At that time there were large factories handling extremely dangerous substances in which no medical care was given the men; they were simply expected to quit the job if they felt sick, indeed they were encouraged to do so in order not to cause embarrassment or expense to the company.

These 2432 cases were almost all men, only seventy-five were women. Not all were seriously poisoned. A fulminate dermatitis was all in 111 cases, an anilin poisoning lasting from twenty-four to forty-eight hours accounted for almost 200 more. The nitrous fume cases were all serious and twenty-eight were fatal; the benzene cases were all serious and seven of the fourteen were fatal. Trinitrotoluene was responsible for 702 intoxications, and though on my list there are but thirteen deaths noted, the information concerning six additional deaths was very positive, but it came to me at second hand and I was not willing to use it. The women were found in the fulminate departments and made up thirty-two of the 111 cases of "fulminate itch." They were also employed in the loading of shell with TNT, and they had forty-three of the 702 TNT cases and two of the thirteen deaths.

At that period in the industry nitric acid and the fumes of nitrogen oxides and atomized acid constituted by far the greatest danger, but the problem of protection against such dangers is mechanical, it is a task for chemists and engineers and as time went on they began to get it in hand While in April, 1916, I saw no less than eight violent outbursts of so-called "nitrous fumes" during a three-hour inspection of a great nitro-cotton works, two years later in that same plant there was hardly one in a fortnight. On the other hand the making and handling of TNT presented a more difficult problem. We knew how nitric acid attacked the body and what lesions it produced; we knew practically nothing about the nitro derivatives of the benzene ring. Indeed before the war the Germans and the British both looked on TNT as almost an ideally safe explosive, inert as regarded the human body, and impossible to explode without a detonator. We learned very soon that the latter was a delusion. All but one of our very disastrous explosions were due to TNT, and as for its action on the body, the fatalities among TNT workers began to become known early in 1916.

It will make the subject much clearer if a brief description is given of the different dangers in explosive manufacture. In making nitric acid and in nitrating cotton for gun cotton and smokeless powder there may be at any moment an escape of fumes consisting of the pale lower oxides of nitrogen and the yellow and orange-colored higher ox-

ides, for when nitric acid comes in contact with the air or with an organic substance a rapid decomposition occurs. Sometimes, especially in nitrating military gun cotton with 100 per cent. HNO_3, the decomposition may be so violent as to blow the lid off the nitrator or centrifuge and reduce the acid to a finely atomized spray which fills the air. When such an accident takes place the men rush for the exits and stay outside till the fumes have cleared away enough to make it safe to go in again. They acquire a good deal of tolerance to these fumes and are able to work in an atmosphere which is quite unendurable to me, but this does not mean a tolerance to a dangerous amount of the fumes. There is no more immunity to nitrous fume poisoning than to nitric acid burns on the skin.

Ordinary nitrocotton for smokeless powder is nitrated usually by the mechanical method, highly nitrated cotton of low ether-alcohol solubility is nitrated by the pot method or direct method. The danger is greater by the latter, but in both the processes of nitration and of centrifuging out the acid—wringing, as it is called—and of washing or "drowning" the cotton from the wringers, are all liable to be accompanied by a sudden "fuming off" with the production of these dangerous nitrogen oxide gases.

A few instances drawn from that survey in 1916 will illustrate the effects of such an accident. A man was working in the pot nitration shed of a nitrocotton plant when a centrifuge blew up and the lid struck him, knocking him senseless. The other men in the shed fled at once before the angry yellow fumes and did not discover for some minutes that this man was missing. When they finally succeeded in dragging him out he had breathed the fumes for some minutes and had drawn them deeply into the lungs. Still, when he came to himself he did not realize that he was injured, he was given the usual first aid treatment of a few drops of chloroform in water with some aromatic ammonia, which quieted his spasmodic cough, and after a couple of hours he was allowed to go home. During the night he woke with a feeling of strangulation, he was obliged to sit propped up in bed, his air hunger and his terror increasing all the time. He had abdominal pain also, but so distressing was his dyspnea that he hardly noticed the pain. The doctor found him unable to speak or move, needing all his strength to breathe, his lungs filled with moist râles, his face livid. In spite of the rather tardy administration of oxygen, he died of edema of the lungs in less than 24 hours after the accident. This case, so similar to the cases of gassing in the trenches, is absolutely typical of industrial poisoning from nitric acid fumes.

When the exposure is less extreme a pneumonia is likely to result, followed sometimes by the lighting up of an old tuberculous process. This was so evident among negroes on the nitrating area that the Du Pont Company decided not to employ negroes in that department, on the ground that they were more likely to have latent tuberculosis than white men. A severe laryngitis, with edema of the glottis, may result from breathing fumes. The older companies, such as the Du Pont and Hercules, instruct the men, if they are exposed to fumes, to take as shallow breaths as possible, so as not to drive the fumes into the whole lung, but unfortunately the instinctive reaction to such fumes is, as I can testify, to hold the breath as long as possible and then take a deep, gasping inspiration and then hold it again. This may result in damage to all the lung tissue.

Erosion of the enamel of the teeth is another effect of the nitrous fumes. Mouth breathers especially may lose all their front teeth. As for the permanent effects of nitrous fume poisoning and the effect of breathing small quantities over a long period of time, no information was to be obtained from the explosive plants. The labor turnover was great, the men did not remain under the observation of any one physician for long, and if they fell ill it was very likely to be in a factory where they had worked only a short time and where nobody knew their past history of exposure. We shall probably learn more about this phase of the question from a study of the later history of cases of trench gassing. In the only instance of industrial poisoning from nitrous fumes in which the victims were followed over a long period of time, it was found that the effects of the accident lasted for months. This was the incident related by Hall and Cooper[1] of Denver, who had under observation eighteen firemen and two printers poisoned by inhaling nitrous fumes from a broken carboy of nitric acid. Four of them died, two from the immediate effects, two from pneumonia developing twenty-two and thirty days after. One-third of the men suffered relapse within three weeks of the accident, and of the sixteen who survived eleven had not yet recovered their health nine months later.

The manufacture of picric acid by nitration of carbolic acid was attended with even more nitrous fume poisoning than was the nitration of cotton, for the industry was, on the whole, less well managed. There were many carelessly run picric acid plants in which the indifference to the safety of the men seemed almost incredible. Some of the worst employed large numbers of negroes from the country districts of Alabama and Mississippi, and the combined effect of a Northern winter, housing in crowded shacks, and exposure to nitrous fumes worked havoc among them, but it was possible to keep the very shocking state of things from the knowledge of the public. To their credit, it must be said that the State labor officials of New Jersey where most of this manufacture went on, labored hard to correct these evils, and gradually succeeded.

Nitrous fume poisoning is not the only danger in picric acid manufacture. The picric itself is poisonous, and so is the phenol. Moreover, the production of phenol for picric involves exposure to benzene a more powerful toxic agent than either. One fatal case of phenol poisoning was reported in the course of this inquiry, many cases of picric dermatitis but only a few of the systemic forms of poisoning with indigestion, abdominal pain, vomiting, diarrhea. Dr. F. O. West[2] of Woburn, Mass., made a study of the urine of picric acid workers with reference to the presence of the acid and evidence of damage to the kidneys. Of 57 men selected for this purpose, 30 had been temporarily affected by fumes in the course of their work, but none seriously. He

succeeded in demonstrating picric acid in the urine of only three, and five contained a trace of albumin. Picric acid is so bitter that men do not swallow much of it. The compound, ammonium picrate, which came into use later on, seems to be quite nonpoisonous.

Benzene in carbolic acid manufacture was responsible for several deaths that year. Usually this was the result of men being sent into tanks to repair pipes, and breathing fumes from the benzene, which was always supposed to have been completely washed out. Very small quantities of benzene are enough to cause serious damage. One case was reported as follows: A man went to the top of a still to see what was wrong. There was a bad leak, and he fainted from the fumes almost instantly, and by the time two others could come to his rescue, which was said to have been not more than two or three minutes, he was dead. Both men who went to help him were overcome and lost consciousness, but were revived. There were also two cases of fatal benzene poisoning in connection with sulphonation of benzene, a stage in the production of phenol.

In England the manufacture of trinitrotoluene seems to have been attended with little if any industrial poisoning; all their reports have come from loading, or, as they call it, filling the shell. That is not true of this country. The making of TNT by nitration of toluene has been attended with a great deal of poisoning, as well as the loading of shell with TNT. The form this intoxication takes is like that of the more slowly absorbed nitro and amido derivatives of the benzene ring. The more volatile compounds, such as the nitrobenzenes, nitrochlorbenzenes, nitranilins, act rapidly, and it is rare to find cases of profound degenerative hepatitis in poisoning from these substances, though the so-called toxic jaundice does occur sometimes. There is also occasionally a case of aplastic anemia from such a compound. I have the record of a case following poisoning with paranitranilin, and another caused by alpha-naphthylamine. But it is chiefly trinitrotoluene* that has caused these two forms of intoxication, acute degenerative hepatitis, and aplastic anemia, in large numbers in Great Britain and in Germany since 1914; and in this country, difficult as it has been to get at the facts, it has been possible to discover a few cases of both forms of TNT poisoning.

In 1916 some 700 cases of TNT poisoning came to my knowledge, and 13 deaths were reported positively, six more were less positive. The 700 include all cases, severe and mild, from a few plants, and the very severe cases from the others. In one plant where the physician was frank and intelligent, there had been about 300 cases, with two deaths. In another, where the physician would give no information at all, five men had died of TNT poisoning, and if the rate was the same here as for the first plant there were 750 cases of less severe poisoning in that plant.

According to W. H. Hudson[3] of the Du Pont Company, who has had much the most experience with this form of intoxication in the United States, the symptoms of what the British call "minor TNT sickness" are as follows: bitter taste in the mouth, gastrointestinal indigestion, constipation, rarely diarrhea. Then severe general malaise, headache, pain in the chest, vertigo, weakness in the limbs. The lips are cyanotic, the skin of the face yellowish. Old chronic cases, or those with repeated mild attacks, develop neuritis of the lower extremities. The men complain also of a bad taste in the mouth, loss of appetite, persistent headache, sometimes nausea and cramps in the abdomen. Others complain more of sore throat, dry cough, sense of constriction in the chest, running eyes, burning in the nose. Almost always they notice that the urine is darker in color. Such a man, if given prompt eliminative treatment, usually recovers rapidly; if neglected, and allowed to keep on in TNT work, he goes on to a more serious stage of the poisoning.

While in Great Britain, physicians connected with the Ministry of Munitions were making a careful study of all forms of TNT poisoning, and publishing their findings for the benefit not only of their own manufacturers and practitioners, but of us Americans as well, we in the United States were pursuing our usual policy of secrecy regarding the dangers in industrial processes, and it was only by rare luck that anything worth while could find its way into our literature on munitions intoxications. The best description of TNT poisoning was given by H. S. Martland[4] of Newark, based on two autopsies which he made, one on a case of toxic jaundice, the other on a case of the more unusual aplastic anemia. In the first he found a toxic hepatitis, with excessive degeneration of the liver, parenchyma, toxic degenerative tubular nephritis, icterus, secondary anemia, showing considerable polychromatophilia. The jaundice in this case was general and extreme. The second case was very typical of the rarer type of TNT poisoning as described by the British. There was a loss of both red and white blood cells, with practically no evidence of regeneration; there were hemorrhages from mucous surfaces; there was no jaundice. Hemorrhages were found in the pericardium and other serous structures, and there was a low-grade parenchymatous degeneration of heart muscle, liver and kidneys, and increased iron pigment in liver and spleen. The bone marrow showed a replacement of erythropoietic tissue by fatty tissue.

In the manufacture of T N T there are in addition to such forms of intoxication as those just described, very rapid forms suggestive of poisoning by some other compound. For instance, Dr. T. H. Harrington[5] of Boston has published several striking cases of this kind. I will quote his description of the first case:

> A carpenter, 42 years of age, employed one week in an establishment where the nitrating of toluene was a part of the process of manufacture, was made dizzy from fumes escaping from a duct under which he was at work. A short stay in the open air revived him. Vertigo and dizziness returned when he remounted the staging. He went home and returned to work the next day. On reaching the working platform he was nauseated, vomited, became dizzy and had to be helped out into the open air. He drove two miles in an open car to his home, during which he was exposed to cold, damp November air. Seven hours later he suddenly grew worse, had convulsions, passed into coma and died at 11.45 P. M. Autopsy confirmed death by gas poisoning.

*Toxic jaundice was caused by exposure to another munition poison, namely tetrachlorethane, which was at first used as a solution in airplane dope, but given up in January, 1917 in Great Britain because of its toxicity.

Cases such as this are believed by some of the British authorities, and by Koelsch of Germany, to be caused by tetranitromethane, not by trinitrotoluene.

After our entrance into the war I was asked to make a second survey of explosives manufactured in the United States, with reference to the incidence of poisoning among the workers. It was evident that much less attention would be necessary to protect employees against nitrous fume poisoning than was required a couple of years before. Great improvements had taken place in the manufacture of nitrocotton, and also in the manufacture of picric acid, although there was still one very large plant making picric acid which left a great deal to be desired. The special danger in 1917 and 1918 was from TNT, both the manufacture and the loading of shell. There was trouble also in the handling of tetryl used for the "booster" charge or detonator.

The reports that had been coming to us from England concerning TNT poisoning in that country had made it evident that there was a difference of opinion as to several points which were important, because upon them depended the proper protection of the men and women handling TNT or exposed to its fumes. In June, 1918, the National Research Council, the Department of Science and Research of our Council of National Defense, determined to take up the study of occupational poisoning in the munitions industry, with a special view to the settlement of these controversial questions, especially in the TNT works. They sent into certain plants in which TNT was manufactured, and others in which shell was loaded, medical students who had been well trained in laboratory methods, in order to collect data as to the danger of dust, fumes, and contact, the absorption and elimination of TNT, and various other points of practical importance. The results of these observations constitute a distinct contribution to the study of TNT poisoning, and are worth a brief summary.

The questions they were especially anxious to solve concerned the following points:

1. The portal of entry for TNT, whether through the skin, or by breathing fumes, or by breathing and swallowing dust.
2. The influence of age, sex, and race on susceptibility to TNT poisoning.
3. How long an exposure is necessary before TNT can be detected in a human system?
4. How long does it take to get rid of the TNT that has been absorbed?
5. What are the earliest symptoms of TNT poisoning?

Of great assistance in making these studies was the so-called Webster test, for the detection of a reduction product of TNT in the urine. This test was worked out in England, and is of great value, making it possible to discover when TNT is being excreted, and therefore furnishing to a certain extent a gauge of the amount that is being absorbed. The test depends on a color reaction, when the acidulated urine is extracted with ether and the ethereal extract treated with alkaline alcohol. The color varies from a faint pink to a deep Burgundy red, and it is customary to describe the reaction by the figures running from 1 to 5.

Four hundred and two workers, only thirty-six of whom were women, were examined in the six plants selected. In one plant toluene was nitrated to TNT. In another, crude TNT was purified and packed. In the other four, shell was loaded with pure TNT and with two mixtures of TNT and ammonium nitrate, known as 50-50 amatol and 80-20 amatol. The plants were situated in northern Wisconsin, in the mountains of Pennsylvania, in the flatlands of New Jersey near the coast, and in eastern Virginia. Negroes were employed in two plants only. As for sanitary conditions, the six plants presented instances of the extremely bad, the excellent, the medium and the poor. The medical service provided would also fall under these same heads. Medical care to be sufficient must include examination of all applicants for employment and careful and frequent inspection of conditions in the workrooms and of the employees while at work, for only in this way can the physician come to know the dangers to which various people are exposed and only in this way can he detect the early symptoms of poisoning. It is not safe to wait for the man to present himself in the office with a complaint of sickness. One plant only had entirely adequate medical care, in two more it was very good, it was fair in the fourth and miserably poor in the fifth and sixth, where the physicians in charge did little more than discharge men and women who they thought might cause trouble and expense to the company by becoming seriously poisoned.

There was a lively controversy last year in England on the subject of skin absorption of TNT versus fumes. Dr. Benjamin Moore espoused the skin theory with great vigor and even went so far as to assert that exhausts for carrying off fumes were a needless expense to the management since poisoning did not take place through the breathing of fumes. Apparently, however, other physicians connected with the Ministry of Munitions insisted on retaining the artificial exhausts that had been ordered and refused to accept Dr. Moore's dictum. We hoped to be able to throw light on this question by selecting groups of workers, some of whom would be exposed to skin contact, others to dust, and others to fumes, but this proved to be practically impossible, partly because the labor turnover was so great that no one group ever contained the same men and women at the end of a fortnight as it had at the beginning, and partly because nobody was exposed to only one kind of poisoning. Every man who was breathing fumes was also coming in direct contact with TNT and the same was true of the men exposed to dust. Nevertheless we were able to arrive at a fairly positive conclusion. This was that, though not the only channel of absorption, the skin is by far the most important one.

Wherever the amount of poisoning was greatest the workers were found to be handling TNT in an easily absorbable form or their skin was dusted over with it. Dusty work did not result in poisoning of a serious kind unless the dust was of such a character as to allow it to pass readily through the skin. Pure TNT when dry is not easily absorbed, although when it falls on a perspiring skin it will cause poisoning, but the mix

tures of TNT and ammonium nitrate are much more easily taken up by the skin because the ammonium nitrate is hygroscopic and the moisture makes the skin more permeable. A man working in amatol has his hands and forearms and other exposed parts of the skin continually moist, in fact one can see tiny droplets of water on the hairs of the arms, and it is these amatol workers who become rapidly poisoned, while men sifting pure TNT or pressing it into demolition blocks are poisoned slowly, if at all.

There was, however, evidence to show the danger of TNT fumes and we would not agree with Dr. Moore that kettles need not be hooded and that fumes from grainers and washing tubs are harmless. A good many cases of sickness have come from just these departments, and in some instances the rapidity of poisoning points to fumes rather than to skin contact. For instance, a new employee went to work the first day stirring a kettle of molten TNT in a pouring room where the fumes were allowed to be very heavy at times. It was a fairly cool day in June, but after a few hours' work he became dizzy and faint and was sent to the doctor, who found his lips blue and his pulse weak and rapid. This was on a Monday and he did not go back to work, but on the following Friday he was still feeling ill and still passing dark colored urine. Another instance of fume poisoning was related to me by a superintendent in charge of the loading of mines and depth charges for the navy. He had under him about 200 men, 150 of them loading mines with molten TNT, and 50 pressing dry TNT for "booster" charges. The two groups worked in separate rooms, the first being exposed to a great deal of TNT fumes from the kettles and from the cooling charges in the mines, and also coming into contact with the TNT, while the other group was not exposed to fumes but was exposed to dust and contact. According to the superintendent, not one man among the 150 engaged in pouring had been able to work for more than three weeks without showing some effect of the poison, and most of them were cyanosed, dizzy, and weak at the end of a week's work. The "booster" men on the other hand had hardly any sickness at all. The superintendent himself came into very little actual contact with the TNT, but he was frequently overcome and had to go out into the fresh air if he was obliged to stay in the loading room throughout the nine-hour shift.

One of the students made an interesting observation on pure fume poisoning. She was attached to a very dirty, crowded, ill ventilated plant, and conditions in the pouring room were excessively bad. On two occasions she remained in this room for two or three hours, being careful not to touch anything during the time. After both these occasions she succeeded in demonstrating TNT in the urine by the Webster test.

It is, of course, by no means certain as yet that the volatile substance given off from molten TNT is not composed of several bodies, among others tetranitromethane. Experiments now being carried on will probably clear up this point.

The second question we sought to answer concerned the influence of age, sex and race on susceptibility to TNT poisoning. With our entrance into the war there was naturally an influx of youthful workers into the munition plants and also of women, although a much smaller number of women were employed in the making of explosives than we had supposed would be the case. Forty per cent. of the employees in the six plants studied were under 35 years of age; 22 per cent. were under 21 years of age. Fortunately the greater number of these youthful employees were employed in two of the good plants.

The student employed in the worst plant noted a distinctly greater susceptibility to TNT poisoning among the younger men. Three lads of 19 years were discharged after three weeks' work because the doctor was unwilling to take the risk of keeping them any longer. One man of 21 years, who was unusually careful and cleanly in his habits, was so sick at the end of the first week that the doctor discharged him. Of all the men who were discharged from this factory during one month on account of sickness, one-third were under twenty-five years of age, yet only one-eighth of the total number of employees belonged to this age group. In the better plants there was no such striking evidence of the over-susceptibility of the young, yet a close analysis of the records brought out the same results. In one very good plant 48 cases of TNT poisoning were selected, 19 of them in middle-aged men and 29 under 21 years of age. It was found that the middle-aged men had worked on an average 49 days before they had noticed the first symptoms of sickness, while the younger men had averaged only 10½ days' work. From two other plants 15 cases were selected in which the history showed that there was a decided over-susceptibility to TNT. All of these men had developed symptoms of poisoning in a very short time, and had had to be transferred to other work. On referring to the age lists, it was found that only one of these had reached the age of 34; the others were under 21 years of age.

As to the influence of sex on susceptibility, the British reports had given us no information because the vast majority of TNT workers in England were women. In our plants just the reverse was true. We had records of only 36 women out of the 400 workers in these six plants and even these women were not employed in any of the more dangerous parts of the work. However, 16 of the 36 were employed in the two worst plants where TNT was spilt and scattered about so carelessly that it was impossible to handle anything without getting some dust on the skin. A group of seven women whose hands were stained from handling shell smeared with TNT were carefully examined. Five complained of slight symptoms, and three gave a moderate Webster reaction in the urine, but none was cyanosed and none had applied for treatment except one married woman who complained of nausea and vomiting and whom the physicians suspected to be pregnant. Another group of nine girls handling small quantities of pure, dry TNT was examined and one, who had been working longer than the others, 24 weeks, showed fairly serious symptoms. None of the others was affected more

than to a very slight degree. The other women were employed under excellent conditions, but ten of them came in contact with amatol and six of these had dermatitis. Obviously unless men and women are employed in the same departments and doing the same kind of work, it is impossible to make any comparison between them. Our studies last summer did not throw any light at all on the question of sex susceptibility.

The same difficulty was encountered when we tried to determine whether the opinion held by practical men that the Negro stands work with TNT better than the white man is based on fact. Unfortunately in one of the plants employing Negroes, the whites and Negroes did not do the same sort of work and there was in addition a great difference between their diet and mode of living. The Negroes lived in their own cabins, ate little meat, and a great deal of fresh fruit and vegetables raised in their own garden. The white men lived in company bunk houses and ate at the company restaurant—a diet very rich in meat, but with almost no fresh vegetables and fruit. Both had plenty of opportunity to take baths in the plant, but the Negroes availed themselves of this opportunity more than did the whites, who were largely from the mountain districts of North Carolina. There are, therefore, several reasons why the Negroes in this plant should suffer less from TNT sickness than the whites. In the other plant which employed Negroes, both races lived in company houses and ate company food, and neither was much given to taking baths. The students attached to this plant could find no difference between the incidence of TNT sickness in the two races. Evidently we shall have to make a more extensive study of Negroes and whites under identical conditions before we can be sure as to this point.

The Webster reaction was what we depended on to show the rapidity of absorption of TNT. It may appear very early. I have already spoken of the student who obtained a faint reaction after two hours exposure to TNT fumes. This same student got a decided reaction in ten newly employed men who had been at work only six hours. An analysis of 133 cases, in which a Webster 5 (maximum) reaction was present, showed that 39 per cent. had not been exposed longer than one to three weeks.

Symptoms of discomfort and distress sometimes appeared on the first or second day of employment, but often these symptoms would pass over and the men would feel quite well for a period and finally developed symptoms of another kind. Often there was a transitory disturbance of digestion with loss of appetite and a bad taste in the mouth, and perhaps diarrhoea, with more or less pain, but all passing over in a few days. The more characteristic symptoms—breathlessness, a sense of constriction in the chest, headache, dizziness, a feeling of "dopiness" and lassitude with pains in the muscles of the calves, weakness of the knees, blue lips and a livid color—began in some cases during the first week or fortnight and persisted. As a usual thing, men who developed symptoms of real poisoning had experienced the first feelings of discomfort fairly early—nearly a third of them before the end of the first fortnight.

If we take the Webster reaction in the urine as a gauge of the elimination of TNT, we find that most men can get rid of all they have absorbed within two weeks after complete removal from the poison, although some take much longer than that. One man continued to give a positive reaction five weeks after removal from TNT work. This is not entirely a matter of individual idiosyncrasy. It depends partly upon the treatment given him to help him elimiate the poison. Repeated tests of the urine showed that a man could get entirely rid of the reaction in his urine in 36 to 48 hours if he were taken into the hospital, given a thorough scrub bath with special attention to the parts of the skin stained with TNT, then given a cathartic, an enema and a diuretic and quantities of warm milk to drink. If, however, he was simply shifted to other work and was allowed to go on wearing dirty overalls and gloves, he might continue to excrete TNT for weeks.

The earliest symptom of intoxication seems to be breathlessness, on exertion, especially going upstairs or climbing a hill. A man who denies that he has been at all affected by the work will almost always admit this symptom if he is asked. Next usually comes dizziness on stooping over, and a more or less persistent headache, or perhaps loss of appetite, bad taste in the mouth and a feeling of nausea in the morning. Men and women working with dry TNT making "booster" charges often complain of running eyes, sore throat, burning in the nose, and nose bleed. Other early symptoms are cramps in the calves of the legs, great fatigue and a sense of tightness in the chest. The change in the color of the urine is noticed very early. At first the color is a clear brown, about as dark as weak tea. Then it may increase till it is as brown as coffee. This color is quite independent of the substance that gives the Webster reaction, for a maximum Webster may be given by a urine with normal color and a dark brown urine may give a negative Webster. In some very serious cases the color is not brown, but deep reddish, and in these cases the Webster reaction is likely to be high. There still remains a good deal of work to be done on the urine of TNT poisoning.

The typical form of severe TNT poisoning is toxic jaundice. During my first survey I had had records of some twenty cases of jaundice, and everything led us to suppose that there would be a much larger number in 1918 because of the much greater number of workers and because of the excessively hot weather in August, for heat always increases the cases of TNT poisoning and their intensity. Contrary to our expectations not one case of typical jaundice developed in the six plants under observation, with the possible exception of a young girl of 16, who was said to have been sent home very deeply jaundiced from one of the worst plants, and was said to have died at home some days later. We were never able to confirm this story.

There are several explanations for the improvement in 1918 over 1916. One is the great improvement in plant sanitation and the even greater

improvement in medical care. In 1916 few physicians knew anything about the prevention of TNT poisoning. No plant had any regular system of shifting the men to safe work when they began to show symptoms of illness, nor had any plant a thorough system of medical supervision. In the summer of 1918 three of the six plants under observation had such excellent medical supervision that it would have been impossibe for a case of sickness to go on to the point of severe jaundice. The two neglected plants were protected by the rule in force that all sick men must be discharged. It is, of course, possible that some of these men developed jaundice later, as we know occurred in several instances among discharged men in 1917, but we have no reports of it. Another factor, and probably a very important one, is the short period of exposure to TNT, especially in the badly managed plants, for in these the labor turnover was truly enormous, the proportion of those employed as long as three months being only 4 and 7 per cent. According to British statistics toxic jaundice usually develops after 8 to 12 weeks' exposure.

The practical points that emerged from this study were the following:

TNT poisoning takes place chiefly, if not wholly, through the skin, and therefore it is essential to protect the workers from direct contact with it by maintaining strict cleanliness of the premises and preventing the splashing of TNT over the outer surface of the shell. Warm, moist TNT is more dangerous than solid TNT. Amatol is more so than pure TNT.

Young people are more susceptible to TNT than the fully grown. They sicken more quickly and suffer more seriously. Negroes are probably less susceptible than whites.

Tests on the urine show that TNT is rapidly absorbed if exposure is great and it can be rapidly eliminated if exposure is stopped. Some men can eliminate over night what has been absorbed during the day. Others can get rid of it over Sunday and start on Monday free from TNT in the system. Therefore a man on an eight hour shift will absorb only two-thirds as much as one on a twelve hour shift, and will have one-third again as much time to eliminate it. A man with one day's rest in seven will be able to stand the work better than a man who works continuously.

The same test showed that the most economical way to treat a workman who is suffering from TNT poisoning is to put him in a hospital and give him vigorous eliminative treatment, and then put him on work free from TNT till his urine is negative. It only prolongs his recovery to give him work that is better than what he has been doing but still involves contact with TNT. Allowing a man to wear dirty gloves and overalls may result in a continual absorption of TNT even if he is put on TNT-free work.

The earlier symptoms of TNT poisoning are short breath on exertion, dizziness on stooping over, headache, fatigue, loss of appetite. These with a positive Webster test in the urine should lead to a temporary shifting from TNT work in order to save the man from serious poisoning.

These studies in munition intoxications were carried on with a view to the protection of the munition worker, but they may serve a purpose in peace-time industries as well. Nitric acid manufacture and the use of nitric acid have not ceased with the signing of the armistice, and nitrous fume poisoning will continue to occur even if we are not making explosives any longer. Picric acid is a fairly important dye. Celluloid and films for moving pictures are made in much the same way as nitrocotton. As for TNT it is said that it may take the place of nitroglycerin for surface blasting. It cannot be used underground because of the poisonous nature of the gases evolved by its detonation, but for surface work it has several advantages over dynamite, being less sensitive and not affected by the cold. Even if it is not used, however, the studies that have been made of its toxicology are of value in helping us to understand the working of the nitro compounds of the benzene ring, many of which are now used in American dye works.

Genital Asthenia.—A somewhat unusual condition described by Professor Loumeau of Bordeaux concerns a finely developed and virile man aged 28 without inherited or acquired antecedents who came for relief from defective potency—incomplete erections which no artifice out of many tested could satisfactorily overcome. He wished to marry. No cause could be found or even surmised to account for the impotence, which was attributed for want of better to some unknown reflex of inhibitory character. Despite his extensive experience Loumeau was not above asking counsel from the Bordeaux Medical and Surgical Society, evidently without regard to individual experience. The point involved, however, was not technical but moral, and hence within the province of all members. Should we recommend the man to marry in the expectation that a wife selected by himself on a basis of mutual affection would bring about a cure? The question has of course often been asked but not often in cases of impotence without apparent motivation.—*Journal de Médecine de Bordeaux.*

Paralytic Rabies.—Marie and Chatelin describe a case of what was primarily a polioencephalomyelitis of rabic origin. The patient was 11 years of age and was bitten on the lip late in October. On December 15 he became paraplegic and in the next three days the paralysis had ascended to the muscles of the trunk and upper extremities. Death was due to respiratory paralysis. Autopsy showed plainly the histological pathology of paralytic rabies of subacute type. The remarks of Professor Netter showed that this opinion was not easily reached. The very earliest symptoms were psychic and the incubation period for a bite on the lip was very long. The animal in the case was "doubtful." There is no mention of any preventive treatment. —*Gazette des hôpitaux.*

New York, June 21, 1919.

CHRONIC OBSTRUCTION OF THE RESPIRATORY TRACT AND SCOLIOSIS.

THE experiments carried out on rabbits by Ziem some years since, unquestionably proved that the complete obstruction of one nostril provokes an asymmetry of the head, thorax, and spine. In order that these phenomena may occur, however, the obstruction must be marked. In certain subjects it may also happen that chronic inflammation of the nasopharyngeal mucosa will favor the development of a deviation of the spine. The state of muscular debility present in subjects having respiratory insufficiency contributes in no small measure to the development of these deformities, and, since their appearance takes place at the time of growth, unquestionably the excess of organic activity which occurs at this time in both the spine and the thorax places the subject in a more accentuated state of receptivity.

The signs characterizing a scoliosis resulting from obstruction of the respiratory tract may be briefly stated to be a barrel-shaped thorax, the anteroposterior diameter being increased while the transverse is diminished, especially at the base. At this point some writers have mentioned a depression corresponding to the insertions of the diaphragm and resulting from exaggerated efforts made by the patient in order to compensate for the insufficiency of the respiratory capacity. The entire thoracic cage appears to have undergone an arrest in growth and contrasts with the development of the other regions of the body. It should be remarked that the obstruction of the respiratory tract is more surely to result from adenoid growths than from hypertrophy of the tonsils and that the deformities of the spine to which they give rise commence to be manifest about the age of from twelve to sixteen years, and it is precisely at this age that, both adenoid growths and enlarged tonsils having acquired their maximum development, the nasal obstruction has become more complete, while the respiratory difficulty, being more marked, produces the thoracic deformity and curving of the spine at the same time.

These scolioses offer the peculiarity that they are not pronounced; they are often dorsal, are more common in girls, and the convexity is more prone to be on the right. They are invariably accompanied by thoracic deformity, and their evolution is slow, never reaching an exaggerated development, at least in most cases. They make their appearance and undergo their evolution during adolescence, especially at the time of growth. The deformity of the thorax resulting from nasal obstruction is commonly observed in childhood and disappears or improves as soon as the nasopharynx has been delivered from its obstruction.

It would therefore appear that in a certain number of cases of scoliosis in adolescents, the primary and determining causative factor of the spinal process is obstruction of the upper respiratory tract from adenoids, nasopharyngeal inflammation, or enlarged tonsils, which are the cause of a diminution of the intrathoracic pressure, producing as a consequence atrophy of the thoracic cage and favoring the development of the scoliosis. Being aware of the multiplicity of causes which may contribute in the production of this deformity, it is clear that one cannot incriminate lesions of the postnasal cavity and pharynx as the sole cause of a scoliosis, but when making an etiological diagnosis careful inspection of the nose and throat should never be overlooked, and often the practitioner so doing will be rewarded for his pains.

HIGH MORTALITY AND CHILD BEARING.

DESPITE the great advance of asepsis and antisepsis, by which the mortality rates of operations have been much diminished, the maternal death rates associated with childbirth are still unduly high. Mr. Victor Bonney, a London obstetrician, in an address recently delivered, an abstract of which was published in the *Medical Press*, May 14, 1919, severely arraigns the methods and lack of preventive measures which render such results possible. It is pointed out that confinements take place in houses unfit for human habitation, and that even in the houses of the well-to-do there is frequently a lamentable lack of preparedness. The public is unaware of the dangers attending pregnancy because the medical profession does not recognize these dangers nor does it hold the view of midwifery held by Mr. Bonney, "that the product of conception is as truly a neoplasm as any other growth within the uterus, and labor a surgical operation that a woman performs upon herself." According, then, to the writer, midwifery is strictly a surgical art which necessitates for its successful prosecution the full gamut of modern surgical requirements, and the only way in which the procedure can be rendered comparatively safe is to regard it from this point of view and to act accordingly.

It is no doubt true that pregnancy, at any rate under modern conditions, is more serious and dangerous than the majority of the medical profession think it to be. It is rational to suppose that if better precautions were taken the mortality from it

would be considerably lowered. Many of the deaths occur from sepsis, which signifies that there is often something radically wrong in the management of labor. Puerperal fever is uncommon in lying-in hospitals and therefore it would appear to be obvious that its occurrence in private practice is due to unsanitary surroundings or want of precautions on the part of those concerned with the cases. The remedy for this state of affairs would seem to be that medical students should have it impressed upon them that labor is a serious condition and that they should be thoroughly trained in the practice of obstetrics. But it is of as great importance that the lying-in woman should be in a healthy environment and should have the best of nursing care. In order that this may become possible there must be a large number of properly equipped lying-in institutions, which will serve not only as places in which sanitary surroundings are assured, but for the training of students and nurses in the technique of obstetrics and in the care of the parturient woman.

In the same issue of the *Medical Press* in which Mr. Bonney's paper appears is a letter from Dr. F. C. Barlow speculating on the immunity from puerperal sepsis of the poor. The writer brings out the ingenious hypothesis that the normal course run by confinement cases in the loathsome hovels of the filthy poor is, first, because the patient is used to her surroundings, and from being continually subjected to a great variety of infection, has succeeded in brewing a polyvalent autogenous antitoxin. Further, it must be added that at such a time a woman's whole system is profoundly modified, it is on a war footing, all power reserves are mobilized and ready to be drawn upon to their fullest extent. Internal secretions are manufactured upon a more extensive scale and there is a general hypertrophy of all organs and a hyperelaboration of all secretions and excretions. This applies only to those who live in very dirty surroundings and have thereby acquired a certain degree of immunity. The rich are in a measure powerless against infection at such a time. They have been trained to rely upon extraneous protection; their healthy surroundings and rational hygienic mode of living become their undoing when once infection does set in; their protection is not, as in the case of the poor patient, an intimate elaboration to suit surroundings and circumstances, but an adaptation of environment modified to suit the needs of the individual over and above these means of protection afforded to the patient in a dirty room. Barlow thinks that her primitive surroundings and relative neglect are often the woman's salvation; there are no prying fingers to examine and help on parturition, and no ill-timed "prophylactic" measures; the tissues are not partially or totally devitalized by antiseptics or irritated into perverted activity by needless interference. *Vis medicatrix naturæ* is often a most trustworthy physician, although but a poor surgeon.

There is some sound reasoning in the above statements. A degree of immunity against infection is acquired by those who live under unsanitary conditions and it does seem likely that the rich are less able to withstand puerperal infection than the poor. At the same time there is no getting away from the fact that the practice of obstetrics is, generally speaking, not performed so skillfully as it should be performed by the generality of practitioners, and that, despite the great advances of the past three decades, there is still room for improvement in this direction. Statistics carefully collected as to the mortality of maternity cases and the causes thereof would be of the greatest value. There is no more important question in the entire field of medicine and surgery than that of obstetrical practice.

THE KIDNEY AND INFLUENZA.

THE general infection arising in influenza not infrequently involves the renal gland. The renal forms of the grippe, not commonly recognized in general, possess so much importance that two distinct classes of patients can be established, namely, those in whom the kidney remains intact and who merely follow the customary destiny of the pleuropulmonary complications should these occur, and, secondly, those patients in whom the kidney becomes involved in the general infection, with the result that the clinical picture, prognosis, and treatment undergo a fundamental change.

In its simplest form the renal involvement makes itself manifest in the shape of a massive albuminuria, while the more serious types are represented by an acute urinogenous nephritis, a number of examples of which have been recorded during the past few months. Between the two extremes, the renal insufficiency assumes intermediary types, particularly the asphyxic form from hyperacute pulmonary edema, which appears unquestionably due to this pathogenesis and represents a pure example of respiratory uremia. The participation of the kidneys may be easily overlooked, because it takes place along with other very serious visceral complications of influenza, and a careful search is required in order to detect it.

The prognosis of influenza is greatly exaggerated by renal lesions and the majority of fatal cases are among those who presented marked albuminuria, while rapidly fatal cases, with death in a few hours from acute pulmonary edema, or in a few days from acute uremia, are the results of renal insufficiency. The study of the renal functions during the evolution of the grippe is, consequently, of the utmost import and requires a daily analysis of the urine. In cases of massive albuminuria the outlook should be regarded as that of renal disease, the influenza itself becoming a secondary matter. Therefore, the treatment of renal insufficiency should at once be resorted to, without awaiting further developments, while should uremic manifestations ensue, the classical treatment must be adopted without delay.

Mortality After Operation for Duodenal and Gastric Ulcer.

Up to the present time investigations dealing with mortality after operation for duodenal and gastric ulcer have usually taken into account only the percentage of deaths due to the operation. A report published recently by Arthur Hunter, chief actuary of the New York Life Insurance Company, considers the effect on the mortality after the operative deaths have been excluded. The materials for this report were gathered from the Mayo clinic, the brothers Mayo having been the first to have statistics prepared from this standpoint. Some very instructive facts were forthcoming as a result of these investigations. The following is a summary of the results: (1) The percentage of operative deaths in the hospital following operation for gastric ulcer was fully twice that for duodenal ulcer, but the percentage in both cases was very low considering the seriousness of the condition. (2) The mortality among persons operated upon for gastric ulcer is three times as high as among those operated upon for duodenal ulcer during the three years following the operation. (3) The mortality among persons operated upon for gastric ulcer decreases relatively after operation, but the data are not sufficiently extensive to determine the number of years which must elapse before the death rate is similar to that of the general population. (4) The mortality of those operated upon for duodenal ulcer in the Mayo clinic is less than that among the general population. Mr. Hunter points out that it is of interest to know that the average age at time of operation of those operated upon for gastric ulcer was 47 in the case of men and 43 in the case of women; the average ages of those operated upon for duodenal ulcer were 44 and 42 respectively. The seemingly abnormally low mortality among those operated upon for duodenal ulcer may be explained largely by the facts that the mortality rate is lower among the individuals from whom the Mayo clinic draws its clientele than among the general population, because there was not a large number of cases, and because all the cases had not been traced.

Fishes and Mosquito Control in Ponds.

The effective control of mosquitos is the chief factor in the eradication of malaria and therefore any measures which will keep down mosquitos are steps in this direction. In Public Health Reports of May 23, 1919, Samuel F. Hildebrand, Ichthyologist, U. S. Bureau of Fisheries, writes from the ichthyologist's point of view as to exterminating mosquitos. His conclusions are as follows: *Gambusia affinis*, the top minnow, is especially suitable for antimosquito work because (*a*) it seeks its food at the surface; (*b*) it is very prolific; (*c*) it gives birth to well developed young, therefore requiring no special environment for depositing and hatching the eggs; (*d*) it lives and thrives under a large variety of conditions and frequents areas especially suitable for the support of mosquito larvæ; (*e*) it usually lives and multiplies in ponds stocked with predacious fishes, providing it has very shallow water for refuge. Plants which have but slightly submerged leaves and stems, on which form floating masses, are the chief sources of protection for mosquito larvæ against the top minnow. Such plants should be removed from the water or treated in such a way as to make them uninhabitable for the immature mosquito. Mosquitos may, however, breed in water so badly polluted that the minnow is almost instantly killed thereby. *Gambusia affinis* eliminates the wiggler completely from ponds which are fairly free from protective vegetation and débris, but even if much protection is furnished by vegetation and débris, the number of mosquitos reaching the adult stage is greatly reduced. The number of top minnows necessary in a body of water to secure mosquito control depends largely upon the conditions which prevail with respect to places of protection, a comparatively small number being necessary, if the water is fairly free of hiding places for mosquito larvæ.

The Saliva in Pellagra.

Even if pellagra be not strictly speaking a deficiency disease, it is, at least, well established that the alimentary tract is involved. The condition of the month, and of the tongue in particular, is of considerable importance in making a diagnosis of pellagra. The true pellagra tongue is of a vivid red color and more or less swollen. Seeing that the oral cavity is obviously involved in pellagra, biochemical studies of the saliva of pellagrins have been made recently by M. Y. Sullivan, Biochemist and K. K. Jones, Food Analyst in the Pellagra Hospital at Spartanburg, S. C. The results of these investigations have been published in Public Health Reports of May 16, 1919. These showed that while there were cases of increased salivary flow, the salivation spoken of by the patients was often apparent rather than real, and was seemingly due to some inhibition of swallowing combined with a peculiar ropy change in the saliva which made its presence in the mouth more obvious. A tendency toward a greater quantity of solids in the saliva of pellagra patients was also observed. The investigations indicate that the diastatic power of the saliva of pellagara patients is at least as great as that of normal people. In no case, whether the flow of saliva was scanty or very copious, was the diastatic power lacking. The reaction of the saliva in pellagra is somewhat more alkaline than is that of normal saliva.

News of the Week.

Opposition to Finger Printing of Drug Users.— Over one hundred members of the Medical Society of the County of New York have signed a call for a special meeting of the society to discuss the amendment to the Sanitary Code of New York City, proposed by Dr. Copeland, which would provide for the finger printing of every patient for whom narcotic drugs are prescribed. The announcement urges a full attendance at the meeting as this amendment is regarded as full of potential danger not only for the present but for the future, and as something which should

not be enacted without the serious and exhaustive consideration of the medical profession. The meeting will be held on Monday evening, June 23.

Red Cross Aids Women's Hospital Fund.—A gift of $65,000 from the American Red Cross to the American Women's Hospitals toward the fund of $250,000 now being raised to send additional units of women doctors, dentists, nurses, and motor drivers, to Serbia and Palestine, was announced recently. This gift will be applied toward the expenses of the unit which will sail for Serbia this month. The gift includes medical and surgical supplies as well as money and was formally accepted at the Medical Women's National Association at its session in Atlantic City on June 10.

Hospital Work in the Balkans.—The first news received from the American doctors who were sent to Albania and Serbia has reached the headquarters of the American Women's Hospitals in New York and describes conditions among the Balkan peoples as appalling. Some parts of the country are said to have been four years without a physician. Dr. Nell G. W. Bartram reports the opening of a thirty-bed hospital at Tirana, Albania, on April 26. Dr. Regina Flood Keyes, stationed at Monastir, writes that they often see as many as 230 to 250 dispensary cases daily. She states that typhus fever in that locality has been about stamped out, but that the number of accidents from explosives is appalling.

Activities of Child Campaign to Be Continued.—The work conducted by the Children's Bureau of the Department of Labor, in cooperation with the committees of the Women's Council of National Defense completed the work of Children's year on April 6, 1919. They report that in the various child welfare activities of the year 17,000 women's committees cooperated. While the final records are not yet complete, the tabulated results of the measuring and weighing tests show that so far 1,619,283 infants have been registered. In addition to the weighing and measuring tests the committees conducted a recreation drive to save children from war time hazards by giving them a chance for summer vacations and by advocating playgrounds. They also opposed the unnecessary employment of children and initiated a "back to school" movement. The work of the year was so successful that in response to appeals from the State child welfare chairman the Child Welfare Section of the Child Conservation Section of the Field Division of the Council on National Defense, will continue to direct this work until July 1, under the leadership of Mrs. Ina J. N. Perkins of Michigan, who succeeded Dr. Jessica Peixotto in January.

Dr. M. I. Black has returned from army service and has resumed practice at 35 West Eighty-first Street, New York.

Congress Asked to Aid Registration of Births.—The Labor Department and census officials intend to ask the next Congress to provide national machinery to record vital statistics, especially births and deaths. The war has shown the great need of complete vital statistics. Most States make registration of all deaths compulsory, while in only 20 States does the registration of births reach 90 per cent. The only national registration of births is through the Bureau of Census, which accepts the figures of such States as reach this standard. The United States is in this respect far behind European countries and the experience of the war has shown that several thousand slackers might have been detected had the Nation had complete vital statistics.

The "Archives Medical Belges," which, though driven out of its own country, nevertheless continued publication during the war, has now returned to Belgium, being published at the Hospital St. Laurent, Liège. It is at present the only national Belgian medical publication in the sense that it is edited in collaboration with all the medical faculties of the country and is thus the exponent of the medical science of Belgium.

Red Cross Starts World Fight on Typhus.—The Supreme Economic Council of the Red Cross League has planned to submit to the governments composing it a plan for combating the plague of typhus in Eastern and Southeastern Europe. The plan includes the placing at the disposal of the Red Cross societies the surgical and medical supplies of the American and British armies. The Economic Council will also provide transportation while the Red Cross societies will supply the personnel. The League of Red Cross societies is appealing to the societies in the United States, Great Britain, France, Italy and Japan, and to twenty-four national societies in other nations to participate in the campaign against typhus. The League states that it feels justified in calling on all Red Cross organizations to do everything they can at the present moment to stop the disease.

Health Problem Presented by New York Indians.—The April Bulletin of the New York State Department of Health is entitled the "Indian Conference Number" and is devoted to a presentation of the health problems presented by the groups of Indians residing in this State. The Department has also issued a special Bulletin stressing certain facts brought out in an investigation of the health situation in the Indian reservations. It is stated that New York State has an Indian population of 5,000 and that these Indians coming into close contact with a million or more white citizens under present conditions are a serious health menace. The Indian has adopted the white man's way of living in houses but does not pay the same attention to light, ventilation, and other sanitary factors. Consequently, he falls an easy victim to tuberculosis and is prone to acquire other communicable diseases and to spread them among his white neighbors. In the last few years the suppression of smallpox on the reservations has cost the State over $13,000. The State Department of Health has made a sanitary survey of the Onondaga Reservation the results of which show the need of teaching the Indian sanitation and personal hygiene and of making the State Department of Health responsible for health conditions on the reservation. At present the Indians are under the charge of the National Government, a system which has not worked out satisfactorily in practice. A bill has recently been signed by the Governor providing for a State Commission to

confer with the Indian Committees of the two houses of Congress in an effort to better the situation. The State Department of Health is about to extend its survey to other reservations, and plans to employ visiting nurses and to develop a comprehensive system of instruction in sanitation which will aid in eliminating the present health menace.

Standardization Plan for Work of Public Health Nurses.—A scheme of organization and plan of work for the public health nurse has been prepared by Dr. B. R. Wakeman, Sanitary Supervisor of the State Department of Health, covering the community nursing service for the health district of Alfred, N. Y. This outline describes the whole plan of organization, the methods of work, and the business organization in admirable form, and is full of suggestions to any rural district employing or contemplating employing a public health nurse. Copies may be obtained by application to the Supervisor of Exhibits, State Department of Health, Albany, N. Y.

United Hospital Fund.—The United Hospital Fund has just distributed $200,000 to forty-four hospitals of New York City. This is $50,000 more than was distributed last year, and the fund at that time was $35,000 in excess of that of the previous year. The fund is apportioned in the basis of the number of days of free hospital treatment given by each institution during the last year. The quality of the individual hospital management is also taken into consideration.

Red Cross Relief Work in Siberia.—The American Red Cross appropriated $400,000 for relief work in Siberia on June 4, this being in addition to what has already been set aside for this purpose. Most of this fund will go for the purchase of drugs and surgical instruments, the need for which has been emphasized in cable messages received from the Red Cross Commission in Siberia. A large consignment of surgical dressings has been shipped from Seattle, including fifteen ambulances, two field kitchens, and six kitchen trailers.

Child Welfare in Westchester County.—Women in Westchester County (N. Y.) who are prominent in philanthropy and have large country homes and estates announce a new movement which has as its aim the care and protection of every child in Westchester County. The plan provides for combining public and private charities in the care of dependent, neglected, delinquent, and defective children, with the object of preventing duplication of work.

Physician Wins Lawsuit.—The Queens County Supreme Court has rendered a decision in favor of Dr. Max Ghertler, a member of the New York City Board of Health, in an action for $50,000 damages, alleging that he was responsible for the death of a man whom he treated in his official capacity. According to the testimony given, a pet dachshund in February, 1917, bit both Mr. and Mrs. Riggs. They notified the Board of Health and were directed to report at the clinic in Manhattan for treatment. After having received fourteen injections of the serum provided by the Health Department, Washington's Birthday intervened and the city clinic was closed. Mr. Riggs, according to testimony, did not want to interrupt the treatment and so he persuaded Dr. Ghertler to treat him at his home. Six days later Mr. Riggs died of blood poisoning. The allegation is that his death was due to improper treatment at this time. The court has cleared Dr. Ghertler of all charges made against him.

Women Physicians Make Appeal for Serbia.—The American Women's Hospitals, which is affiliated with the Red Cross, began on June 1 a campaign to raise $250,000 to pay the expenses of equipping and transporting to various points in Serbia the hospitals, doctors, and nurses which the Government of that country has officially requested the organization to furnish for the purpose of fighting the epidemic of typhus fever which is now raging there. It is stated that only 140 physicians are left in Serbia, and that large areas of country are without medical service of any kind. While in this country there is one doctor to every 1,000 people, in Serbia there is one to every 21,000. The personnel of the unit which is to be sent has been selected and is headed by Dr. Mary M. Crawford of New York.

Obituary Notes.—Dr. EDWARD LINDEMAN of this city was drowned at Atlantic City on Thursday of last week. He was attending the meeting of the American Medical Association, and is believed to have died of heart failure while swimming at some distance outside the breakers. Dr. Lindeman was born in 1879 and was graduated from the Johns Hopkins Medical School in 1908. He had done a good deal of special work in blood transfusion, and had presented a paper in the Section on Pharmacology and Therapeutics of the American Medical Association on "The Critical Period in Various Diseases Treated by Blood Transfusion."

Dr. JOHN H. THOMPSON of this city died on June 7 at the age of 84 years. He was a graduate of the New York Medical College in 1863. He was at one time visiting surgeon at the Homeopathic hospital in Ward's Island.

Dr. MGURDITCH SIMBAD GABRIEL died at his home in this city on June 3 at the age of 63 years. He was born in Elghin, Armenia, and was graduated in 1881 from the Central Turkey College, Aintab. He came to this country in 1886, having been banished by the Turkish Government because he wrote a work on "The Regeneration of the Armenians." He was a member of the Medical Association of the Greater City of New York, of the Medical Societies of the County and State of New York, and of the American Medical Association.

Dr. JOHN T. NAGLE, for many years connected with the Health Department of New York City, and an authority on vital statistics, died at his home in this city on June 14, at the age of 78 years. He was born in Vermont and was graduated from the New York Medical College in 1864. He served with distinction in the medical department of the U. S. Army during the Civil War. He was a member of the Medical Societies of the County and State of New York, of the American Medical Association, of the American Public Health Association, and of the New York Academy of Medicine.

Correspondence.

GERMAN PHYSICIANS AND AMERICAN MEDICINE.

To the Editor of the Medical Record:

Sir:—In the Medical Record of June 14 I note, under the heading, "A Plethora of German Doctors," that there is a possibility of German practitioners coming to this country after the signing of the Peace Treaty, unless measures are taken by the authorities to refuse them a license to practise.

The patriotic American physicians of this country gave up their practices to serve in the army and navy, and many will return to find these practices entirely lost. We cannot afford to have German physicians come here and compete with us. Not only should they be denied a license to practise in this country, but they should be denied admission to the country. The records of their inhumanity in the treatment of wounded soldiers is sufficient in itself to prevent them from associating with members of the medical profession. There was a time, perhaps, before the war, when physicians of the world might have been considered as constituting a brotherhood. The German doctor has placed himself without the pale, and it is not likely that in this generation he will be readmitted to medical fraternity.

I wish to register my objection to any German physician coming to this country, and will endeavor to do all in my power to prevent it, and I think other physicians will be of the same spirit. Personally, I can neither forget nor forgive, nor is there any likelihood that time will cause me to relent.

E. P. Robinson, M.D.

New York.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, May 22, 1919.

Women in Industry.—The report of the War Cabinet Committee on Women in Industry which was presented to Parliament in the last week in May is a valuable document containing an enormous amount of information upon industrial circumstances before and during the war, as well as many wise suggestions for future reform. The committee making the report is a strong one, consisting of Mr. Justice Atkin, a distinguished Judge of the High Court; two learned lawyers, Sir L. L. Macessey and Sir W. W. Mackenzie, both of whom have specialized in industrial affairs; Dr. Janet Campbell, one of the medical officers to the Board of Education; Mrs. Sidney Webb, a well known writer on industrial subjects; and Sir Matthew Nathan, who is acting as secretary, and who after having been soldier, consul, and administrator, is now secretary to the Pensions Board. The committee was appointed by Mr. Lloyd George in his character of chairman of the War Cabinet Committee, with instructions to investigate the relation which should be maintained between the wages of women and men, having regard to the interests of both and the respective value of their work. It came into being in September, 1918, and it was an instruction to the committee that their recommendations should have in view the necessity of output during the war and the progress of industry in the future. At the time of appointment the war was at the height of its intensity, but two months later came the German collapse, clearly making the prognosis of events to come more important than the maintenance of an intensive output of munitions or material or foodstuff for military use. The recommendations of the committee receive the endorsement of all save Mrs. Sidney Webb, though Sir William Mackenzie made certain reservations. The gist of the recommendations directly concerning the future relation between men's and women's wages is that women doing similar work or the same work as men should receive equal pay for equal work, the pay being proportionate to efficient outcome; and the Government is urged to support the application to industry of the principle of equal pay for equal work, applying it with the least possible delay to their own establishments. Mrs. Webb's objection to the principle of equal pay for equal work is that the exclusion of women by law or custom from the better paid posts means that the equality promised will only be equality in bad circumstances, equality in good circumstances never being offered. But the most noticeable part of the report is a memorandum by Dr. Janet Campbell on the Health of Women in Industry. She discusses physiological differentiations of the sexes as they have an influence on fatigue and on nutrition, and on the functions of maternity and lactation. She sets out the effects of the employment of women on their general health under the heading of anemia, overstrain, general sickness incidence, and tuberculosis, and gives her reasons for thinking that the sickness incidence among women is greater than it is among men, and that industrial occupation gives rise to anemia, to overstrain from fatigue, and tuberculosis. The precise effect of employment on motherhood she does not find easy to estimate. The most striking part of Dr. Janet Campbell's Memorandum is a list of appended recommendations directed to the Government. These recommendations point out the necessity of reasonable wages, of further investigation by scientific methods of the physical effect of employment upon women, and of substantial reform and extension in scope of the Factory and Workshop Acts. They are a model of clear thinking and direct speaking.

A National Conference on Infant Welfare.—Under the ægis of the National Association for the Prevention of Infant Mortality and for the Welfare of Infancy a National Conference on Infant Welfare will be held as part of the Baby Week celebrations at the Kingsway Hall, Kingsway, London, W. C. 1, on July 1, 2 and 3, from 2.30 to 4.30 each day. Under the presidency of Dr. Christopher Addison, M.P., president of the Local Government Board, the following subjects will be discussed; Antenatal and neonatal mortality; the prevention of, and the work of the midwife in, antenatal and neonatal mortality; the industrial employment of mothers in relation to infant mortality; and the illegitimate child. The conference follows aptly upon the report of the War Cabinet

Committee on Women in Industry which I make a note of elsewhere. Sir Francis Champneys, the well known obstetrican who presides over the Midwife's Board; Sir Arthur Newsholme, until lately the principal medical officer of the Local Government Board, and many publicists and philanthropic workers will take part in the conference, whose proceedings gave a dismal interest from the low birth rate and high rate of infantile mortality revealed by the last vital statistics of the country.

The Prescribing of Cocaine.—An Edinburgh doctor was recently fined £1 at the Edinburgh Sheriff Court for giving a patient a prescription for cocaine, on which the words "not to be repeated" did not appear. The chemist who made up the prescription was likewise fined. There was no suggestion of any other offence except forgetfulness, and as the prescription was one for a throat gargle, in which carbolic acid also appeared, and which was therefore quite impossible for any other purpose, the imposition of this fine would seem to be at first sight an excessive punishment, but such are the dangers of cocaine indulgence that most medical men, though ready to sympathize with their colleague, will endorse the rightness of the sentence. The particular act of carelessness may have had no great danger attached to it, but it is necessary that every available precaution, either laid down by the war or suggested by prudence, should be taken against any laxity in the dispensing of cocaine.

The Pathology of London Transport.—The conditions of transport in London are so actively bad now that they are absolutely producing a pathology of their own. London stands on an area of 800 square miles—that is London proper—and is ringed about, in a radius of more than 30 miles with cities and villages which shelter workers whose daily employment brings them into the heart. For this vast concourse of people thus implied, across these great stretches of country, no proper railway, tramway, or bus accommodation exists. More people stand than sit in some of the railways, and they stand in cruel jams exchanging emanations. To get on to a bus, especially at busy hours in early morning or late afternoon infinite patience is required to await a bus where there may be room, and pronounced athleticism may be required from him or her who would board the vehicle. There is no steamboat traffic, and the trains are hopelessly overcrowded. Thousands of persons who have to work hard all day are thinking throughout the day of the mad struggle in which they will be engaged later if they wish to be conveyed to their homes, thus avoiding what may be a walk of many hours. There is no doubt that the strain thus added to the day's labor is telling on the London industrial and commercial population severely—actually as many as 30 or 40 people have been known to faint in the South London trains in one day! Many medical men, individually, are urging upon Parliament the need for immediate reform of the London transport. It is to be hoped that some collective medical movement will be taken.

The Growth of Cremation.—Cremation grows but slowly in this country, where custom, ecclesiastical prejudice, and economy alike lead the public to prefer the old-fashioned form of burial. The annual report of the Cremation Society of England for 1918 shows that the number of cremations at Woking was 142, as compared with 129 in the preceding year, whilst the corresponding figures for Golders Green were 820 and 719. The total number of cremations for Great Britain during 1918 was 1795, against 1515 for 1917, every crematorium having returned an increase in cremations. Through the courtesy of the author of a well-known book of reference I learn that in 1918 the United States of America had 70 crematoria and that upwards of 14,000 cremations were carried out in the course of the previous twelve months. It would be interesting to British medical men to know if the medical profession in America supported the cremation movement by precept, example, or purse. In our country, though the initiating steps were largely taken by a deceased and famous ovariotomist, Sir Spencer Wells, the medical profession has taken no interest in reforming the old-time usage. Medical jurisprudents have actively opposed cremation on the ground that all evidences of medical poisoning would thus be destroyed immediately after death, which disinterment has before now led to the conviction of murderers, whose connection with the death, not suspected in the first instance to be a crime, had gone unnoticed. Is that an American view, also?

LETTER FROM CANADA.

(From an Occasional Correspondent.)

TORONTO, May 31, 1919.

Venereal Diseases in Ontario.—According to Capt. Gordon Bates writing in the *Canadian Public Health Journal* for May, 1919, it is estimated that of the population at large about 8 per cent. are syphilitic, and easily available statistics for Canada would appear to bear out this statement. Eight per cent. of the total population of Canada infected with syphilis means conservatively 500,000 cases. When it is further borne in mind that in military hospitals the number of gonorrheal patients under treatment greatly exceeds the syphilitics, and that doubtless conditions in civilian life are similar, the gravity of the situation can be well realized. Capt. Bates points out that a great deal remains to be done in Canada in the direction of controlling venereal diseases. The fringe of the problem has only been touched notwithstanding the existence of legislation, while no organized attempt whatever has been made to deal with the question of prostitution. It is a matter of common knowledge that clandestine prostitution exists on a large scale in Toronto and in other Canadian cities. Montreal possesses a "red-light" district which is probably not surpassed by any American city and some of the Western Canadian cities bear an unenviable reputation for prostitution. A Federal Department of Health should serve to coordinate and help forward the work.

A Canadian Department of Health.—It is announced that the Hon. N. W. Rowell has prepared the first draft of the proposed bill to be intro-

duced in the Canadian Parliament, to establish a Federal Department of Health. This bill will be largely framed on the lines sketched in our Canadian letter which appeared on April 26. The Department will be in charge of a Minister of the Crown, with a Deputy Minister of Health, who shall be the deputy head of the Department and who shall hold office during pleasure. Such other officers, clerks and employees as are necessary may be appointed in accordance with the provision of the Civil Service Act, all of whom shall hold office during pleasure. The duties and powers of the Minister in charge shall include all matters relating to the promotion and preservation of the health and social welfare of the people of Canada. The following names have been associated with the post of the Deputy Minister of Health: Lieut. Col. John A. Amyot, C. M. G., Professor of Hygiene, University of Toronto; Lieut. Col. T. A. Starkey, Professor of Hygiene, McGill University; Dr. Peter H. Bryce, Chief Medical Officer, Department of the Interior, Ottawa, and Dr. Hibbert W. Hill of the Minnesota Public Health Association, and formerly director of the Institute of Public Health, London, Ontario.

Regulation and Care of the Feebleminded.—The feebleminded, unrestrained and unrestricted, are a menace to a country from many points of view. Perhaps, especially is their presence in large numbers a source of danger because feebleminded girls are the most potent means of spreading venereal disease. In the large majority of cases prostitutes and women who give themselves up to promiscuous intercourse are either feebleminded or on the borderland of that condition. For a long time the immigration into Canada of feebleminded individuals has been deprecated by those who have the true welfare of the Dominion at heart, and now steps are to be taken to regulate the admission of immigrants. The control of immigration by selection, the establishment of institutions for the feebleminded, and all problems affecting the social welfare of the country will be the subjects calling for new legislation.

It is probable that plans will be made whereby prospective immigrants to Canada will be examined in Europe by Canadian medical men. Dr. Clarke and Dr. Hincks of Toronto are likely to go to Europe late in the summer to make arrangements to carry out this scheme. Mr. Hearst, the premier of Ontario has announced recently that the Ontario Government will issue a grant of $119,650 for the erection of buildings for the Orillia Hospital for the feebleminded. It will thus be seen that in Canada the problem of the feebleminded is to be grappled with vigorously. It is assuredly one of the most serious problems of the day, and it should be everywhere faced boldly and not evaded as has been hitherto the case.

A plea for the better and more careful treatment of the insane and those suffering from mental diseases marked the address of Dr. C. K. Clarke at the first annual meeting of the Canadian National Committee for Mental Hygiene, which took place in the general hospital, Toronto, on May 30 last. Dr. Clarke urged that preventive methods were necessary and also careful supervision of individual patients at the asylums by a force of field workers in psychiatry. Through the cooperation of the University of Toronto the Department of Public Health, the Asylums of Mimico and Toronto and the Social Service Department of the Toronto general hospital, this course had been made possible, and a trained force of workers in this branch would soon be available for the various asylums. Col. Thomas Salmon, U. S. Army, who had charge of this branch in the U. S. Army in France gave the committee an outline of the work done in the United States as regards mental hygiene. It may be said that the Canadian National Committee for Mental Hygiene has done already valuable service. It has made a thorough survey of the Province of Manitoba to discover the number of mental abnormals and their method of treatment and its recommendations have been embodied in legislation.

Decrease of Communicable Diseases in Ontario.—There has been a gratifying decrease in the number of cases of communicable diseases in the Province of Ontario for May, although there is an increase in the number of deaths. The latter feature of the monthly report of the Provincial Board of Health is due to the fact that influenza and influenzal pneumonia and primary pneumonia are included in the statistical table this year, whereas last year no such returns were made. There is a continued decrease in the number of cases of influenza and pneumonia. Influenza and acute influenzal pneumonia caused about the same number of deaths each while acute primary pneumonia caused three times more deaths than the two other forms combined.

The Manufacture of Salvarsan.—A good deal of discontent has been expressed in Canada recently with regard to the regulations regarding the manufacture and importation into Canada of Salvarsan and allied products and other arsenical preparations employed for the treatment of syphilis. It is generally thought by members of the Canadian medical profession that permission should be at once granted for the manufacture of Salvarsan or similar preparations. All German patents should be regarded as forfeited by the war, and articles made under patents granted by the Canadian Government to citizens of Germany should now be thrown open to Canadian enterprise and capital. This should include all drugs, chemicals and dyes. The medical profession of Canada and Canadians generally are of the opinion that the Germans should not be let off lightly. They forced the war upon the world and caused an awful cost of life and treasure and should not be allowed to resume pre-war conditions. There seems to be a tendency now to let down Germany easily. This view, however, does not hold in Canada.

Illness of Lieut. Col. Nasmith.—Lieut. Col. George G. Nasmith, C. M. G., Director of Laboratories, Department of Health, Toronto, has been seriously ill for the past three months. Col. Nasmith has done splendid work in France and in Canada, and all who know him are sincerely glad that he is now regaining his health.

Medical and Health Meetings in Toronto.—During the week beginning May 26, there took

place in Toronto the annual meeting of the Ontario Medical Association, the Canadian Public Health Association and the Ontario Health Officers' Association. These meetings will be dealt with in subsequent letters.

2. N. C. A. Neurocirculatory Asthenia.—Joseph H. Barach points out that N. C. A. is a syndrome found in certain individuals in whom the nervous or the circulatory symptoms may predominate. Under this heading are found cases of "Irritable heart of the soldier" and the group designated by the English as D.A.H. Strictly speaking, it is primarily not an affection of the soldier, but of the civilian of whom it has been attempted to make a soldier. Nor is the condition primarily the affection of a disordered heart, and therefore the term neurocirculatory asthenia, or N.C.A., seems the most applicable. The predisposing factors appear to be hereditary and acquired: a bad family history, a bad environment, previous disease, physical and psychic injury. Most of the patients, according to Lewis, are in the twenties, and 23 per cent. give a history of rheumatic fever. The exciting factors which convert a potential case into one of N.C.A. may be any physical shock, and certainly the conditions that exist in modern warfare, such as prolonged marching, intense fighting, terrific bombardment, shell shock, gassing, burial, trench fever, dysentery and infected wounds. The subjective symptoms are, feeling of shakiness after exertion, breathlessness, fatigue chest pains, palpitation, giddiness and faintness, after physical strain. The chest pain of true angina is substernal, whereas in N.C.A. it is precordial. Extrasystole is very common. Other complaints are, tinnitus, backache, muscle pains, stiffness, nausea and vomiting, night sweats, enuresis, unpleasant dreams, disturbances of speech and voice, irritability, and lack of power of concentration. The objective symptoms are, fine and coarse tremor of extremities and muscles of the trunk. The posture is faulty at times. Pseudoanemic pallor; at times flushing and dermographia. Hands and feet are cold, clammy and cyanotic; there is axillary sweating, hyperalgesia of the chest wall, exaggerated reflexes, diffused apex impulse and pulsating abdominal aorta. The pulse rate is accelerated, there is irregular heart action, respiratory arrhythmia, extrasystole, occasionally bradycardia, poor response to exercise phosphaturi and oxaluria.

2. Postinfluenzal Psychoses.—Egbert W. Fell reports that in an epidemic of influenza of average severity occurring in soldiers who were for the most part between the ages of 20 and 30, only four of 2,500 cases treated at the Walter Reed General Hospital, Washington, developed psychoses of a severe type which outlasted the acute disease. Twenty cases of postinfluenzal psychoses were treated in the psychiatric wards of that hospital. These cases fell into three fairly distinct groups: Manic-depressive group, 8 cases; infective-psychosis group, 7 cases; dementia precox group, 5 cases. Predisposition as shown by the family or personal history was only marked in the manic-depressive group. There was a sufficient overlapping of the groups to give, when considered as a series, a gradation from a simple depression to hebephrenic precox of the depressed type. The characteristic of the series is: a foundation of depression on which develops sense falsification, confusions, and schizophrenic symptoms. The author points out that the occurrence of precox symptoms is not a sure indication of permanency, but such cases run a longer course and recovery is less likely. The most common symptom was depression. Hallucinations seemed to be entirely absent in seven cases.

1. The Croonian Lectures on the Rôle of the Sympathetic Nervous System in Disease.—W. Langdon Brown pays a warm tribute to the memory of Gaskell, who first showed that the nerve fibers which flowed from the spinal cord into the sympathetic chain were of a smaller caliber than the nerves to the skeletal muscles, and that there are fibres with visceral functions in the cranial and the sacral nerves which subserve the functions of organic life and are not under the control of the will. Such visceral fibers are now usually included under the term autonomic nervous system, introduced by Langley. The visceral or involuntary nervous system may be classified as, (1) the sympathetic (thoracico-lumbar outflow); (2) the para-sympathetic: (a) cranial outflow; (b) sacral outflow. The essential parts concerned in a reflex action are the receptor and excitor elements. The former in most cases does not connect directly with the excitor, but there is an intermediate neuron, bringing the two into relationship, for which Gaskell suggested the name "connector element." The connectors need not simply associate receptors and excitors of the somatic nerves in the same level of the cord; they may run up and down in longitudinal tracts, bringing neurons of different levels into relationship. In the autonomic system there is a connector preganglionic medullated fiber and an excitor postganglionic nonmedullated fiber, and just as the connector element of somatic nerves may run longitudinally in the spinal cord, so the connector element of visceral nerves may run longitudinally in the sympathetic chain; and as in the process of evolution the receptor cells have been withdrawn from the periphery into close proximity to the spinal cord, so the excitor cells of visceral elements have migrated out from the cord into outlying ganglia. The purpose of this different arrangement in the two systems is found in the different functions performed: the somatic nerves are for localized accurate reflexes, the visceral nerves are for widespread diffuse effects. The results of sympathetic stimulation serve to activate the body for a struggle and to increase its powers of defense; and since the mechanisms for self-defense which we now possess were developed in the course of vast periods of time, it is to be supposed that some are not suited to our present needs. The pilo-motor fibers are an example of this. Some emotional responses, like some of our bodily structures, are vestigial remains. There are

certain features of general resemblance between the sympathetic and parasympathetic. They both control functions of organic life and act apart from the will. They are both composed of small medullated connector fibers and conform to the rule that efferent autonomic impulse runs from the central nervous system to muscle or gland without having a nerve cell on its course. In the sympathetic, the fine medullated preganglionic connector fiber springs from a cell in the lateral horn; it passes out in the anterior root, which it leaves by a white ramus communicans, to enter the sympathetic chain. It ends by forming synapses round cells in the lateral or in the more outlying sympathetic ganglia, such as the superior cervical and mesenteric ganglia. Thus a single connector fiber may stimulate a number of cells. From these cells start the nonmedullated postganglionic excitor fibers, which pass to their destination, mainly along blood vessels to the deeper parts and along spinal nerves to the more superficial parts, being distributed to the latter by the grey rami communicantes. In the parasympathetic the postganglionic fibers are distributed direct to the peripheral tissues, branching as they go. They have their cell station close to their destination and their effects are more localized. The function of the cranial portion of the parasympathetic may be regarded as anabolic, while the sacral division, which consists of the pelvic visceral nerve, is mainly a mechanism for emptying. It was Gaskell who pointed out that when the sympathetic and parasympathetic are distributed to the same structure, the effects are antagonistic. In pain, fear, rage, and any intense excitement the sympathetic neurons are brought rapidly into play, and the action of the cranial division of the parasympathetic is inhibited; the anabolic activities of the body are in abeyance and the katabolic activities go on unchecked. The one exception to the rule that connector fibers are not distributed direct to muscle or gland is the adrenal nerves, which are preganglionic. Phylogenetically, embryologically, and functionally the adrenals and the sympathetic are in the closest association. The chromaffin cells appear to originate in the central nervous system, and when in evolution the sympathetic cells emigrate into outlying ganglia they are accompanied by the chromaffin cells. This explains why in the adrenals alone the connector fibers end and why, as Langley pointed out the effect of adrenalin on any part is the same as stimulation of its sympathetic nerve, for the chromaffin cell represents the excitor element. In the adrenals we have a most interesting example of the correlation of nervous and chemical stimuli. The sympathetic excites a secretion of adrenalin, and adrenalin increases the sensitiveness of the response to the sympathetic. Emptying of the adrenal reservoirs occurs not only in direct stimulation of the splanchnics and in strong emotions, but also in trauma and acute infections. This mobilization of adrenalin lowers the threshold to sympathetic stimuli, increases the blood sugar, hastens the clotting of blood by increasing the amount of prothrombin and diminishes muscular fatigue. The thyroid is another endocrine gland which has close relations with the sympathetic nervous system, and like the adrenal, it can be thrown into increased activity by the sympathetic, and in turn increases the response to the sympathetic. The main thesis of this lecture is that the stimulation of the sympathetic and its coadjutors, the adrenals and the thyroid, means the spending of reserves in the supreme struggle for survival. The quickening of all the vital processes may produce, for a time, a feeling of exaltation and well-being. This may be regarded as a physiological justification for Nietsche's injunction to live dangerously. But exhaustion lies in wait if the struggle is unduly prolonged. A viscious circle is the pathological equivalent of a prolonged struggle. Next, under physiological conditions the sympathetic acts as a whole, while one of the phenomena of disease is dissociation. Sensory dissociation is seen, for example, in tabes and syringomyelia. Sympathetic dissociation may play a part in diabetes and in disorders of digestion and circulation. Evolved in subconscious plane, the sympathetic remains forever beyond the control of the will. The higher centers of the brain show their influence on the lower chiefly in the direction of inhibition. The highest organism is the most self-controlled, but the sympathetic cannot be thus controlled. Though we may deaden the emotion, we cannot prevent the response to an emotion once evoked. To regulate this we must trust to reserves, inherited and maintained through generations of stable and equable ancestors. The lecturer concludes with the remark that we might modify the dictum that the war would be won by the nation with the strongest nerves and say that it would be won by the nation with the strongest adrenals, for just as character is revealed in the instinctive response which occurs quicker than thought, so the great powers of tenacity and endurance may be clearly foreshadowed in the original emotional response.

1. The Medical Tradition.—Sir John Tweedy comments on the changes now taking place in the profession of medicine; the air, he says, is thick with projects of reconstruction and change—the regimentation of medicine, a Ministry of Health, and trade unionism with its bargaining, strikes, and picketings. Although changes may remove existing defects and herald improvements, experience teaches that reforms are often followed by unexpected evils and reformers are too apt to think that change necessarily implies betterment. He contends that any change, whether effected from within or imposed from without, that restrains the liberty or lessens the responsibility of the medical man, or hampers the free play of his intellectual activities, will be detrimental to the authority and usefulness of medicine and prejudicial to the interests of public health and national welfare. The part played by medicine in the national welfare has been strikingly shown in the recent war, and though the brilliant triumphs of medicine have been partly the results of the labors of our predecessors and partly the outcome of the researches and investigations of contemporary workers not only in medicine but also in the allied sciences of chemistry, physics and biology, the victory was eventually assured by the thousands of trained workers who knew how to make full use of the resources which science had placed at their disposal. Medical men of different nationalities and race, reared under different educational and social systems, were able to cooperate because they had inherited the same traditions of rational medicine. But medicine is probably destined to play an even greater part in peace, for it holds the promise, if not the actual potency, of preventing all preventable diseases and curing all curable ones. Its influence will be determined by the intellectual ability, the personal character, and the moral endowments of the individual practitioner. To go back to first principles, all that is necessary may be found in the writings of the ancient Greek physicians, and especially in those of Hippocrates, using this name in the generic sense. Although it is impossible to determine with precision the philosophical and medical ideas of Hippocrates in an historic sense, it is easy to determine them in a traditional sense. Nature does not change and though we have other names and other forms of disease, other means of healing, and other ideas, to become a great physician the same qualities are necessary today as formerly, and the underlying principles of medicine are the same. In "The Ancient Medicine" Hippocrates observes that medicine has for a long time been in possession of a principle and a method. Guided by these, many useful discoveries have been made and further discoveries will inevitably be made if capable men, instructed by former discoveries, take them as a starting point for their own researches—or, seek from

the known to discover the unknown. The principle and method of medicine are observation and reasoning. Pre-Hippocratic medicine was mostly observational and experimental, but with Hippocrates it became ratiocinative.

As Hippocrates remarks in commenting on the Onidian sentences, any one, without being a physician, can describe the symptoms and termination of each particular malady simply by asking the patient what he suffers, but the physician, unable to discover hidden disease by direct vision or by what is told him by the patient, searches for it by reasoning. As at the present time, there were critics of medicine in the days of Hippocrates, who, in replying to them, says that there are bad physicians but also good ones; that medicine is not infallible and not omnipotent; it cannot go beyond nature, repair the irreparable, or perform miracles. It therefore rightly refuses to undertake the treatment of incurable cases. This advice was not absolute, however, for he remarks over and over again that it is the duty of the physician to do good to the sick, and at least not to do harm; and the practitioner is advised that if he does undertake the treatment of a desperate case, he should always take care to commit no fault. Four hundred years later Celsus wrote that it was the duty of a prudent man not to undertake a case which he could not cure, nor to subject himself to the imputation of having destroyed a patient destined to die of his disease. Galen gave similar counsel, but Avicenna, the famous Mohammedan physician of the eleventh century, struck a note more in harmony with modern sentiment when he wrote that we should never seem to abandon a patient and up to the last moment should endeavor to soothe, but we must not gamble with a life by powerful remedies and big operations where there is no well grounded hope, otherwise we render ourselves voluntary homicides.

Today the teaching of Hippocrates still holds good: the natural powers are the healers of disease and the physician is the servant or minister of Nature. The physician should observe closely the operations of Nature and follow their indications, fortifying and controlling when necessary. As in the arts of agriculture and politics, the military art and the art of navigation, there can be no absolute certitude in medicine. The most skillful physician can never be sure of curing his patient, but he can be sure of employing all his knowledge and skill according to the established rules of his art. Hippocrates names six conditions necessary to become a skilled physician: natural talent, instruction by a competent master, a place favorable to study, education begun in youth, love of work, and long application; and the first of these is the most important. Theory should be combined with practice, and practice must be supplemented by literary study. The personal character and habits of the physician are only second to intellectual ability and professional training, and friendly and confidential relations should be cultivated among members of the profession. Medical ethics, as embodied in the well known Oath, were settled once for all by Hippocrates. In the Hippocratic writings two kinds of secrets are referred to: trade secrets, which were considered sacred and were only revealed to the initiated but which have practically ceased to exist in modern medicine, and secrets of trust which are referred to in the Oath and today are inviolable except under compulsion of a court of law. Of late, however, there has been a tendency on the part of legislative and administrative authorities to encroach on the principle of professional secrecy. In regard to abortion, Hippocrates was ethically far in advance of the prevailing opinion of his day. Under certain circumstances, the practice was sanctioned by Plato and Aristotle, who were both influenced by social, political and economic considerations, for in the Greek commonwealth, over-population and pauperism was a terror looming closer every year. Hippocrates' view was based on an ethic of universal validity, and it should never be forgotten that medical philosophy is essentially an ethical study and that he who in the right spirit devotes himself faithfully to the practice of medicine engages to an equal degree in the service of humanity.

4. Autoserum Treatment of Chorea. Alan Brown, George E. Smith, and John Gordon Phillips.
5. The Treatment of Pulmonary Tuberculosis in Children by Artificial Pneumothorax. E. Stolkind.

4. Autoserum Treatment of Chorea.—Alan Brown, George E. Smith, and John Gordon Phillips refer to the bacteriology of chorea and point out that there are a large number of observers who believe that Sydenham's chorea is essentially a manifestation of rheumatic fever and that it represents an organic disease of the brain which attacks all parts of the cortex equally and impartially. Other observers, while admitting the association of chorea and rheumatism, believe that chorea represents a functional disturbance due to a variety of causes, and among these causes infection is one, and of the infections rheumatism is the most common. Attention is drawn to the fact that A. L. Goodman of New York in 1918 was attracted to the subject of chorea therapy when two of his cases developed classical symptoms of miliary tuberculosis and died. At autopsy it was found that the tubercles were restricted mostly to the central nervous system. It occurred to the observer that the inability to bring about a complete cure was due to the fact that all previous methods employed were ineffective in that they did not reach the seat of the trouble, which exists in the central nervous system. In view of the fact that chorea is generally recognized as a bacterial disease due to a streptococcus of the viridans group, certain antibodies must perforce be in the circulating blood plasma, which antibodies do not enter the cerebrospinal fluid on account of the choroid plexus, which does not permit of the transmission of these antibodies into the spinal canal. When the serum is injected into the canal a certain chemotaxic action takes place, and the walls of the choroid plexus again become permeable. With regard to the technique, it is most essential that both tuberculosis and syphilis be excluded, and that all drug therapy be suspended for at least five days previous to the injection. The first step consists in withdrawing about 50 c.c. of blood from the median basilic nerve. In some instances an anesthetic is necessary, as the patient is often too nervous to keep still sufficiently long to obtain the amount of blood required. Ethyl chloride is the anesthetic employed. It is important to have the tourniquet applied just tight enough to impede the arterial flow; of course one soon empties the arm of the venous blood, and no more can be obtained until the tourniquet is released. A good plan in this connection is to use a blood pressure band on the arm and have it inflated to about two-thirds of the blood pressure. The blood is received into three sterile test tubes, the rubber tubing and needle having been previously sterilized and held, so that the opening in the test tube is protected from contamination by a piece of sterile gauze wrapped about the rubber tubing down to its point of entrance into the test tube, the gauze from there on being held about the test tube. The tubes are stoppered with sterile plugs and set aside for a few minutes to allow the blood to clot. Before putting in the centrifuge a sterile platinum loop is run down inside each tube to separate the clot from the test tube in order to obtain the greatest amount of serum possible. The test tubes are then put in the centrifuge for thirty to forty minutes. At the end of that time the serum is drawn up in a sterile pipette, emptied into a sterile test tube and put in the incubator to keep at the proper temperature for injection. In the first few cases of these writers, the serum was inactivated before injection. At present they are omitting this, trusting to their technique to keep the serum sterile. From 50 c.c. of blood they obtain 20 to 25 c.c. of serum. The preparation of the serum takes about one to one and a half hours. The patient is prepared as for lumbar puncture. As they always give an anesthetic, no breakfast is taken. The serum is drawn into a 20-c.c. Record syringe, which fits the ordinary lumbar puncture needle. The patient is then anesthetized with ethyl chloride, the needle inserted, and about 20 to 25 c.c. of spinal fluid withdrawn. The Record syringe is then attached and the serum slowly

injected. This is the crucial step in the operation, as it is essential to give as much serum as possible without causing pressure symptoms as one slowly injects the serum; when sufficient has been injected one feels definite obstruction to the entrance of the serum. Further injection, after this resistance has been encountered, invariably results in marked pressure symptoms, such as vomiting, severe headache, elevation of the temperature, etc. An anesthetic is necessary to enable one to detect this sense of resistance. In the writers' series of cases they used on an average 17 c.c. of serum. Results as follows: 1. Autoserum therapy in the authors' hands has been productive of infinitely more satisfactory results than any other form of therapy, a cure of 77 per cent. of the cases being effected within three weeks time. 2. The technique is so simple that it may be employed in any home or outpatient department under mild anesthesia. 3. With the observance of proper precautions the reactions are negligible. 4. There have been so far no recurrences in over a period of a year and a half, but more time is necessary in order to give a more certain decision on this point.

Archives of Pediatrics.

1. On the Present Frequency of Acute Otitis Media and of Subsequent Mastoid Operation in Some Measure a Reproach to Pediatrics? Thomas S. Southworth.
2. Intravenous Injections in Infancy. Advantages of the Superior Longitudinal Sinus Route. Earl Mendum Tarr.
3. The Excretion of the Vitamines. A. M. Muckenfuss.
4. A Case of Influenzal Meningitis. Charles Kimball Johnson.
5. Masking an Entire School to Prevent the Spread of Influenza. Nathaniel Barnett.

1. Is the Present Frequency of Acute Otitis Media and of Subsequent Mastoid Operation in Some Measure a Reproach to Pediatrics?—Thomas S. Southworth says so far as he knows, no progress has been made during the past decade, or, one might safely say, for a much longer period, toward definitely aborting acute otitis media. We may probably grant that prompt paracentesis of the drum has largely decreased the number of persons suffering from chronic disturbances of the middle ear, since we believe that it relieves congestion and pressure and often prevents the development of a suppurative process. We may further admit that the mastoid operation has saved many lives that would otherwise have been sacrificed, but if we may judge from their common occurrence very little has been accomplished by way of prophylaxis for these two conditions. Paracentesis and mastoid operation appear to be placed in the same category as immediate operation for appendicitis, the view in each instance being that the earlier the operation the less the danger of serious later developments. There is, however, this difference, that removal of the appendix or mastoid cells eliminates future danger from that particular source, while paracentesis is only a temporary protective measure with no absolute guarantee for the future, and possibly occasionally furnishing an avenue for the entrance of further trouble. The author's chief desire in writing this article, however, is to arouse interest in the search for prophylactic and abortive measures, of which we stand in great need. Acute otitis media, although one of the commonest of afflictions arising in pediatric practice, has not, so far as the author knows, been made the subject of any investigation from a pediatric standpoint, our knowledge and procedure being dictated by otology. Formerly earache was treated by the instillation of various ear drops into the auditory canal. These have been largely swept into the discard by the aural surgeon as inefficient or as obscuring his field of vision. Aside from the antiquated use of laudanum and hot oil, so strenuously objected to by the otologists, there have been more recent combinations of cocaine, adrenalin, carbolic acid, alcohol, glycerin, etc., designed not only to relieve pain but to reduce engorgement and act antiseptically by absorption or osmosis. Should we not again ask ourselves whether they had absolutely no efficacy; whether they could not be made to have abortive power in a certain percentage of early cases, which might thus be spared paracentesis with its very real discomforts, if not real danger of transforming a simple effusion into a purulent one by contamination from the external auditory canal. Having been taught to fear the spray for cases in early life, Southworth has long substituted dropping into the nose oil, albolene, plus such antiseptics as eucalyptol, as being less liable to penetrate the tubes, or, in the event of so doing, carrying with them bactericidal properties. While distinctly helpful in combating coryza and nasopharyngeal infections, this procedure does not always prevent the development of an otitis. The principle, however, of the instillation of oily solutions of antiseptics, possibly with oil of greater specific gravity than albolene, would appear to be capable of further development for purposes of prophylaxis. Southworth concludes by asking these questions: (1) Are there any therapeutic measures which tend definitely to prevent middle ear infections in acute nasopharyngeal conditions? (2) Are there any abortive measures which are reasonably efficient in beginning otitis media? (3) Could not some such measures be devised by well directed research? (4) Are we correct in assuming that immediate early paracentesis is always indicated in all cases of effusion into the middle ear? (5) To what degree and under what circumstances, after paracentesis, is the pediatrician justified in counseling delay in the presence of the classical indications for mastoid operation? (6) Is the frequency of acute otitis and of mastoidectomy inevitable, or is it due to a complacent neglect of further research in this field? Those questions are well worthy of study.

March 1, 1919.

Unfavorable Vital Statistics of Spain.—Dr. Gomez Ocana shows that the outlook of Spain for inhabitants is grave. Thus, in regard to the death rate, this in 1912 was 21.6 per 1000 population. During the next four years the average was slightly in advance of that figure, while in 1917, before the advent of the pandemic, it shot up to 26.16. The natality for the same period has on the whole shown a decrease, although in 1916 for some unknown reason it reached a maximum of 33.8. With this exception there was a steady decline from 31.60 to 29.2. Apparently the official figures for 1918 are not yet available; but some idea may be obtained from the Madrid figures for that year. As a result principally of the pandemic, the death rate of that city rose to 30.37 while the birth rate fell to 26.70. Not all parts of Spain have shown this destructive tendency, for in the Canary Islands the death rate showed improvement up to 1917, but this fall was associated with a parallel fall in natality.

Varicella and Benign Variola.—Dr. Hernandez Briz in charge of the San José Asylum recently saw a double outbreak of these affections in the latter institution. He recalls that even the great Virchow made a diagnosis of smallpox in a severe case of chicken pox which in some manner terminated in death. Diagnosis was made after histological study, apparently of a biopsy specimen. There is no reason, if a varicella lesion becomes infected with ordinary pyogenics, why it should not suppurate and leave an indelible scar. Until the day arrives when a bacteriological test is available we shall have no sure criterion of diagnosis between these affections—meaning, of course, severe varicella and benign variola. We can never foretell when a supposed varicella will communicate to an unvaccinated subject the most virulent smallpox. In the asylum 15 to 20 children from 1 to 2 years of age had recently had chicken pox. All were robust and while some had been vaccinated others had not. Then as a result of the appearance of a case of variola everyone in the asylum was vaccinated or revaccinated. Failure to take was followed up by further attempts. The vaccination was in every way a success and those who had just had chicken pox were all included in the positives, with one exception. A girl of 6 months, unvaccinated, had apparently recovered from her varicella which was mild and simple in type. To the surprise of all she developed apparently a relapse of confluent varicella (?) with possibility of benign variola. She was isolated and eventually recovered but a positive diagnosis was impossible.

GENERAL MEETING ON MEDICINE.

DR. WALTER L. BIERRING, CHAIRMAN OF THE SECTION ON PRACTICE OF MEDICINE, IN THE CHAIR.

Proteose Therapy by the Intravenous Method.—Dr. P. NOLF, Lt. Col. of the Belgian Army, Professor of Physiology of the University of Liége, Belgium, presented this topic. He said that active measures directed against infectious diseases before the war could be divided into three groups: (1) vaccines, (2) sera, (3) specific chemical substances. According as one used one or the other, these were classified as vaccinotherapy, serotherapy, chemotherapy. In the last few years a new therapy had been developed, called proteose therapy, consisting of protein administration, such as casein of milk for instance. The administration could be made by means which avoided the action of digestive juice, as by the subcutaneous, intramuscular, or intravenous method. Proteose therapy was first used in cases of hemorrhagic diathesis in which there was increased coagulability of the blood. In paroxysmal hemoglobinuria the paroxysm was temporarily inhibited. During the war proteose therapy was introduced in the treatment of infectious diseases by making use of peptone, which, when given intravenously, was capable of producing intense intoxication, characterized by incoagulability of the blood, fall of blood pressure, a certain marked excitability of the autonomous nervous system, spasm of the bronchi leading to emphysema, nausea, vomiting, etc. This condition had been called protein shock, being specific for proteins and being produced by animal or vegetable toxins of characteristic protein nature, foreign to the human being. Such proteins had been called antigens. Shock could be produced in the dog by injecting a little defibrinated blood taken from the dog itself. The same result could be obtained in human beings. Serum freed from corpuscles gave the same result upon injection. Simple coagulation of the plasma transformed it into toxin for the species from which it was taken, that is, turned it into an antigen. In place of serum, red corpuscles could be used, by placing them in distilled water, and, after hemolysis, adding sodium chloride. Such a solution acted like peptone, if introduced into the vein. If an antigen were given over a sufficiently long period of time, the animal became more and more sensitive, and more nearly approached the anaphylactic state. Anaphylaxis was merely an exaggeration of protein shock. This shock could be regarded as an effort of the organism to fix and assimilate the antigen introduced into the veins. No matter what the antigen, the shock was found to be identical in character. Provided the passage into the blood stream took place slowly, no shock would be produced. In the treatment of infectious disease, one should avoid shock, but a mild reaction, or peptone effect, seemed advantageous. It was better to inject small doses into the vein rather than under the skin. This procedure should be performed only by a physician acquainted with the dangers of the technique. It was necessary to inject the peptone slowly, watching the pulse carefully. Slight tachycardia, headache, and febrile reaction might take place, passing off within a short time. Defervescence was accompanied by profuse sweating. Signs of diminution of the infection followed, and improvement was noted after one or two injections. This treatment had been applied by the author with good results in typhoid fever, in streptococcus and staphylococcus septicemia, in which case the germs disappeared from the circulating blood, and it had exerted favorable action in erysipelas and in nonrheumatoid arthritis. As the process was essentially nonspecific, it could be given in conjunction with specific measures to bring about a cure. It had been used in conjunction with hexamethylenamine and with sodium salicylate, in streptococcic and staphylococcic septicemias and in acute arthritides.

New Plan of Improvement of National Health in Japan.—Dr. SENICHI UCHINO, Chief Medical Officer of the Expert Sanitary Control Board of the Home Department, Tokyo, Japan, read this paper. The speaker said that the National Health Bureau had taken up plans for the preservation of national health, under the control of the Minister of the Home Office. Plans for Infant Welfare, Health of School Children, Control of Venereal Disease, Improvement of Food and Housing, Hygiene of the Farm, and Organization of Vital Statistics were formulated. The Health of the nation was to be studied and causes detrimental to its progress were to be eradicated. Means of improvement were sought and all these factors were to be dealt with statistically so that causes and remedies were accurately stated. It was found necessary that personal investigations should be made in pioneer Western countries and consultations should be held with those versed in the special subjects indicated. New plans were organized during the present war and as these were to be continued for several consecutive years, no report was as yet ready.

Some Differences Between Influenza Pneumonia and Pest Pneumonia.—Major S. T. LEE, Surgeon Major, Chinese Army and Chinese Delegate to the Interallied Sanitary Conference, Paris, presented this topic. Major Lee said that he had only a few minutes warning to prepare a speech at this meeting, therefore, his contribution would be in the form of extemporary notes. He said that last fall, when passing through this country to return to China, he heard much discussion as to whether the "flu" epidemic originated in China, the home of many curious and undesirable things. He would take this opportunity to present some differences between the pest pneumonia epidemic in China and the postinfluenzal pneumonia. In 1910-11 there was an epidemic of pest pneumonia in China, with a death total of 50,000 and no recoveries. This occurred in Manchuria and Northern Mongolia, spreading along the Chinese Eastern railways and lines of travel. In 1917-18 another epidemic with a death total of 12,000 took place in Southern Mongolia through the highways passing through the great wall. A third epidemic, localized in the central province of Sujan, took place this year, with 83 deaths. These epidemics had been proved to be due to plague and plague only. They took place in the winter months among the poorer classes. A Plague Bureau was instituted at Harbin, which had been able to keep the northern part of Manchuria free from plague. The influenza epidemic of 1918 broke out in unconnected villages, often separated from each other by uninfected areas. In some places the nervous types predominated, in others the gastrointestinal types of the disease; there were few pneumonic types. Reports of plague, typhoid, and dysentery came from these places, but investigation showed that the disease was influenza. In regard to clinical differences, in influenzal pneumonia the lung symptoms persisted longer, there was more marked nervousness, and the pneumonia was a secondary complication superimposed on the primary disease. In plague pneumonia 48 hours was the average course of the malady; in influenza three to four days. In regard to epidemiology, plague pneumonia occurred during the winter, whereas the grippe pneumonia was at its height in autumn. Plague pneumonia occurred among the poorer class, but the influenza pneumonia occurred among all classes indiscriminately. In plague pneumonia direct contact was necessary to contract the disease, but infection was often hard to trace in influenza. Nurses and doctors taking proper precautions did not contract plague pneumonia, but they frequently contracted influenzal penumonia.

Pre- and Post-war Impressions in the Balkans.—Dr. JOHN CONSTAS, Delegate of the Greek Army, gave an informal talk on this topic. He said that Greece, and also the unfortunate nations of Serbia and Montenegro had been at war since 1912, so that the peoples had suffered more in proportion, with the duration of the war. Commercial and medical supplies had been more interrupted. The treacherous and brutal Bulgars

had proved the axiom that "birds of a feather flock together" by finally joining the Teutonic forces in spite of the persuasions of the Allies. At the beginning of the world war, the Greeks, under the rule of Constantine, the tool of the Kaiser, were kept from joining the side of nations fighting for humanity. However, it was psychologically impossible that a nation, whose ancestors first gave the world democracy, should be kept back from their right to fight for freedom. The Greek nation passed through a very trying period, and during the days when the Mediterranean swarmed with submarines the true state of affairs of the Greek and Serbian armies and medical service was never known, although later when channels of news were cleared the facts began to sift through. The frightful scourages of typhus and influenza as they affected the Serbian people were then appreciated. One-fifth of the Serbians perished due to disease conditions. If it had not been for the angels of mercy from America, with nurses and ambulances, these terrible diseases would never have been checked. The whole sentiment of Serbia, Albania, and Montenegro was one of heartfelt gratitude and more than gratitude for the American aid. None of these nations would ever forget what this country had done for them, so long as the earth should circle in its course.

SECTION ON PRACTICE OF MEDICINE.

First Day—Wednesday, June 11.

DR. WALTER L. BIERRING, DES MOINES, IOWA, IN THE CHAIR.

Chairman's Address: Relations of Internists to Military Medicine.—Dr. WALTER L. BIERRING of Des Moines, Iowa, presented this address. Medical army officers, he said, had, in the first place, been simply known as army surgeons, although allied branches, such as sanitation, bacteriology, and internal medicine had contributed to military medicine. Twenty-nine base hospitals had been first established, but this number was rapidly increased. The importance of tuberculosis having early been recognized, well-known internists had been employed in organizing this branch, as also that of cardiovascular disease. The officers of the Medical Reserve Corps had been trained to learn army organization, and men accustomed to a hospital service of 40 to 50 beds became used to the handling of 1,400 to 1,600 beds, the number running as high as 4,700 in the influenza epidemic. Although the environment of the sick soldier was different to that of the patient in civil life, medical knowledge had been much increased by military conditions. Such problems as the control of respiratory infections, meningitis infection, nephritis in the young, trench fever, effort syndrome, diabetes, had received much light. Medical men had lived in ideal conditions for study, with active cooperation of all branches and the freedom from professional competition. This was bound to lead to the establishment of groups of specialists with coordinated professional activities, which would add greatly to the welfare of the civilian population. It would be found when the history of the war was written that the services of internal medicine had played an important part.

The Basal Metabolism and Alimentary Hyperglycemia Tests of Thyrotoxicosis.—Dr. GEORGE W. MCCASKEY of Fort Wayne, Ind., presented this topic. The present status of the study of thyroid disease, he said, was what the study of diabetes would be without laboratory data. Often in thyrotoxicosis the thyroid gland was not even palpable. One had therefore to look beyond the goiter. The differentiation of borderline cases and the determination of toxicity were two important points. The tachycardia, nervousness, hyperhidrosis, and later digestive disturbances were simply the expression of the toxemia. The clinician was constantly confronted by doubtful cases and there must be some measure of the rise and fall of the thyrotoxic symptoms. Basal metabolism bore relation to the neuromuscular and secretory phenomena, such as respiration, circulation, secretion, a hyper-state corresponding to increased metabolism and a hypo- to decrease rate. Metabolism corresponded to heat consumption or oxygen consumption and the apparatus of Benedict had been designed to measure this production, as estimated by the number of calories per square meter of body surface per hour. A 10 to 20 per cent. increase in consumption was coincident with the mild cases, up to 50 per cent. moderate, 60 to 70 severe; 70 to 100 very severe. The metabolism tests were subject to marked variations and the reading was good only for the time of the experiment. It was, however, of undoubted value in studying the course of the disease. In regard to the hyperglycemia tests—100 gms. of glucose fed to normal persons did not produce hyperglycemia in one hour; in hyperthyroidism there was an increase of 100 to 200 per cent. in one hour. Every reading of over one-tenth of one per cent. represented hyperglycemia when tested with fasting stomach. Even in border line cases a marked hyperglycemia was noted. An increase in basal metabolism and a hyperglycemia, while not actually pathognomonic, formed most valuable corroborative evidence of thyrotoxicosis.

Dr. JOHN C. HEMMETER of Baltimore said that it gave him pleasure to listen to a paper that had a physiological basis. Dr. McCaskey had made use of a practical method to test disease of the thyroid. He, however, took certain things for granted by assuming that the process of oxidation in the thyroid was increased, and that there was hyperglycemia when a certain amount of glucose was in the circulation. Dr. Hemmeter had seen the apparatus spoken of, and had noticed no provision for observing the humidity of the patient given off as expired air. An 80 per cent. humidity would make a great difference, by increasing the percentage of sugar by 13 per cent. There should be a correction of the figures. He did not wish to go through all the agonies of sugar metabolism, but a hyperglycemia in the blood after 100 grams of glucose was really physiological. The method would seem therefore to require further revision. Sugar might not exist in the blood as sugar, but combined with something else, as a chloride. One had to be careful not to push conclusions that were physiologically not proven. In sugar metabolism one was confronted with a physiological paradox. In the hyperthyroid cases one saw a furnace that refused to burn paper, while it would handle anthracite coal. The organism could break up the protein molecule, and even the carbohydrate moiety of the protein molecule, but it could not break up the carbohydrate molecule, the easiest of all. It was the case of "Water, water everywhere," or rather "sugar, sugar everywhere, but not a drop to use."

DR. LEWELLYS F. BARKER of Baltimore said that these two tests should be of value in clinical medicine. In the determination of thyroid disease there was a question as to whether or not one was dealing with over activity of the thyroid gland. The methods seemed to be complex but were in reality tolerably easy. Metabolism was certainly increased in this condition—Graves' syndrome—and this was an easy way to measure. it. Hyperglycemia did seem to be increased, but this was not that the body did not split the carbohydrate molecule, it meant that sugar was mobilized more quickly at that time, because if it could burn the carbohydrate moiety of the protein molecule, of course it must be able to break down sugar. Whether this was direct result of thyroid activity remained to be seen. The relation of the thyroid product to cell metabolism all over the body was to be considered, as also that to other endocrine glands, such as the suprarenal. Many of the thyroid phenomena could be traced to hypersuprarenalism. These tests were no doubt valuable, but difficulties existed which had to be overcome.

Dr. N. W. JANNEY of New York City said he had been interested for a long time in the aspect of carbohydrate metabolism. He thought more accurate work was needed on the technique of the tests. With the careful addition of liquid per kilo, he had got more accurate carbohydrate curves, that is, using 1.75 grams sugar per kilo with 2.5 c.c. water to dissolve the glucose. Hyperglycemia seemed to be indicative of the hyperthyroid condition, but glycosuria seemed to have no special relation. These tests should be studied so as to apply to the borderline conditions, where they were most needed. Precisely these same curves had been found in pituitary conditions and in a few cases of

Addison's disease. The apparatus of Benedict was by no means so simple as it appeared to be. Much further investigation was needed along these lines.

Dr. G. W. McCaskey said that all one ever found was one-tenth of 1 per cent. sugar in the blood. It could be followed fairly closely. In regard to humidity, the error would be as great fasting, as after the dose. What they had was the test for comparison. That was the practical point. These tests were not entirely pathognomonic of thyroidism, but to a disturbance of the endocrine system in which the gland was overstimulated at one time or another. The pancreas probably did not respond to the overstimulation and therefore was not interfered with. It was not entirely a question of oxidation, but of metabolism. It might be impairment of liver storage or failure to store glycogen in the muscles. Certain measurements per kilo of weight should certainly be estimated. One did not as a rule get hyperglycemia in normal cases.

Classification of Goiters.—This paper was read by Dr. H. S. Plummer, Rochester, Minn. He said that the normal thyroid developed from prenatal acini with epithelium, and a certain percentage contained fetal rests or cells capable under certain conditions of producing acini. The thyroid elaborated two products: thyroxin and colloid. Colloid was associated with the formation of the hormone, but played no part outside of the thyroid gland. Exophthalmic goiter was a distinct clinical entity sharply differentiated from other conditions of hyperthyroidism. The profession had been slow to accept this theory. The thyroxin was present in all the cells of the organism in quantum of potential energy on the oxidation of the cells, and the amount of energy transformation varied with the amount of thyroxin in the cells, being increased in hyper- and decreased with hypo-thyroidism. Five thousand cases had been studied at the Mayo Clinic with regard to metabolism rates. An average of 39 calories per hour per square meter of body surface was normal. In hypothyroidism, 35 per cent. below normal, 7-10 mg. thyroxin was required to maintain normal balance. Exhaustion of the hormone in normal individuals varied with total energy transformation, and could shift 100 per cent. in normal persons, the basal rate remaining constant. With a dose of thyroxin the basal rate rose, then later dropped back. Under ordinary conditions the thyroid need not eliminate its product. The increase of energy could be met in other ways, by increasing stimulation of the cells, or chemical changes as in the adrenals. In regard to structure, nearly normal glands were removed in mild cases. In the hypertrophic gland there was increase in colloid and number of acini, formation of new tissue with adenomatosis. All this might be found in the same gland. Stimulus of fetal rests resulted in colloid goiter. In adolescence there was often diffuse deposit of colloid and adenomata were often deeply embedded. Two forms were seen: nodular colloid goiter and colloid adenomata. These were clinically indistinguishable from adenomata and had the same clinical indications. Hypothyroidism was associated with low metabolic rates, sometimes it was seen with adenomatous goiter, in a milky form with constitutional states, and not often clinically recognized. Many cases diagnosed as hypo- were really hyper. Myxedematous individuals never gave history of goiter. In the hyper- cases, the extirpation of the adenoma brought the basal metabolism to normal in three weeks. In exophthalmic types there was probably some variation of the thyroid hormone from the normal. These cases were distinct from hyperthyroidism.

Dr. Emil Goetsch of Baltimore said that he had been working on these problems for 5 years. The symptoms of hyperthyroidism were due to toxin elaborated by the thyroid gland, and one could assume that there was thyroxin in all the cells of the body, and that the symptoms were an overaction of the nervous system, probably the sympathetic, which would give hyperaction of the body cells, just as, for instance, the cells of the gastric mucosa were stimulated to hyperacidity in this condition. Dr. Plummer's theory that the hormone is altered in exophthalmic types was interesting. No doubt exophthalmic goiter was a clinical entity. The thyroid was stimulated to overactivity by a method not understood. The disease was not primarily in the thyroid gland. Exophthalmos was never produced by thyroid medication, nor could it be obtained experimentally by the hormone. The exophthalmos was probably the result of irritation of the sympathetic system, the patient becoming poisoned and at operation the removal of the poison empirically relieved the patient, but left the exophthalmos still present, though not as the result of thyroid secretion. At Brigham Hospital they had found the metabolism strikingly parallel with the symptomatology of the disease, and the oxygen consumption and incidentally the adrenal in hypersensitiveness ran parallel with the course of the metabolic activity. In cases which improved this rapidly fell. As regards groups, there were the colloid, the hyper, or adenomatous types, and thirdly exophthalmic types. It was hard to tell whether adenomatous types were active or not. These being new tissue, did not follow the laws of tissue growth. The metachondria was not a functional activity of all cells and usually disappeared. Adenomata, becoming cystic, often became inactive through degeneration and a spontaneous cure resulted. Symptoms depended upon the balance between amount of secretion and the tolerance of the individual; when this was exceeded, intoxication resulted.

Dr. L. F. Barker of Baltimore said that one should understand clearly what a man means. Much confusion could be avoided if one recognized that Dr. Plummer did sharply distinguish between exophthalmic goiter and hyperthyroidism. In the literature this division had not been made. Usually Basedow's disease had been regarded as hyperthyroidism. Probably one would come, in time, to speak of "Plummer's Syndrome," meaning classical exophthalmic goiter, as distinct from hyperthyroidism. While both conditions were due to over thyroid activity, the symptoms, prognosis, and treatment of exophthalmic types were different. In regard to classification on the pathological and histological side, one point should be made which affected treatment. Adenomata of the thyroid or nodular struma produced symptoms best treated by surgery, and operation gave quicker results. In the exophthalmic goiter operation also gave better results, but it was difficult to be sure what form one was dealing with clinically. Protrusion of the eyeballs was sometimes present in adenomato, sometimes not so in typical exophthalmic goiter. Sometimes one saw marked tachycardia, nervousness, and sweating, with obesity and some of the obese patients were improved with thyroidectomy. A study of a large number of cases, such as at the Mayo clinic, was of great value to science.

Dr. Henry A. Christian of Boston said that there were three tests of value: determination of basal metabolism; relation of blood sugar to ingested sugar; determination of blood pressure to injection of adrenalin. These were not pathognomonic of changes in the thyroid, but depended upon disturbances in the body, commonly associated with thyroid disturbance. They were more valuable as measures of function than of diagnosis. The basal metabolism tests were of more value than the others as the changes occurred more regularly. It was, however, necessary to sound a warning against measuring the patient in figures of basal metabolism, as the figures only expressed the metabolism at the time of the test. Some such changes were temporary, but some were permanent, resulting from prolonged disturbance, and these would not be modified by removal of the gland. Thus one might see patients with thyroid activity measured by increased basal metabolism of 60 to 70 per cent., showing relatively few of the cardinal symptoms of exophthalmic goiter in marked degree, and operation on these cases would cause a serious disturbance, because without the basal metabolism one would not have recognized the severity of the disease. In another type the basal metabolism is little increased, but the patient showed cardinal symptoms of exophthalmos together with permanent cardiac disturbance—in such a case basal metabolism was less than the clinical picture; operation would not produce any great change because the permanent cardiac damage had been done, as the result of thyroid activity. In considering these points, mistakes could be avoided in the disproportion between the clinical picture and the tests, otherwise many errors would be committed.

Dr. G. W. McCaskey of Fort Wayne, Ind., said he was always glad to hear Dr. Plummer's views, but he had injected a difficulty into clinical work, that was in the question of slow introduction of thyroxin into the circulation. This fact was difficult to correlate with that we could have changes in basal metabolism of 100 per cent. in the course of a few days. This he had seen happen. The most interesting group of cases were the borderline cases. Hyperthyroidism was not suspected until one found metabolism 45-60 per cent. increased. Was this a separate group and something akin to the hyperchlorhydria which appeared in these cases? Could the thyroid react without definite clinical disease, as did the glands of the stomach?

Dr. Charles H. Mayo of Rochester, Minn., said that Dr. Christian had covered the surgical indications. No one had yet found a sensible answer to the question as to why the thyroxin reacted on the eye and produced the protursion of the eye ball. There was a typical exophthalmic goiter without the exophthalmos. Under the microscope the tissues were seen alike and producing excessive secretion. The discussion here would do more to make a new classification of thyroid disease than ever before. There had been a jumble from the surgical standpoint, but now one went so far as to remove a part of normal thyroid, to reduce excess of secretion, if there was no reason for medical treatment.

Dr. H. S. Plummer of Rochester, Minn., said that the details of the subject were tremendous, but there was a fundamental fact, and that was that the thyroid hormone did control the rate of splitting of the carbon molecule, that is what one called life, that made a phenomena as complex as physiology plus medicine, plus sociology. It was, therefore, better to stick to basic facts. The presence of adenomata raise the physiological rate. To say that hyperthyroidism is an incident in exophthalmic goiter might be correct, but it was misleading. All the symptoms were due to the thyroid hormone, but it was likely that the hormone underwent some modification in the relation of the iodine content, but this did not invalidate the theory that other physiological changes first occurred in the body. If one removed enough tissue from the patient with Basedow's disease, that patient was no longer hyperthyric. One did not have hyperthyroidism with a normal basal rate, but there were cases in which hyperthyroidism passed off leaving the exophthalmos. Physiological hyperthyroidism could not be recognized unless the rate was above 20. Of the cases so diagnosed, not one-fourth were really hyperthyroidism. The condition known as irritable heart in the army had nothing to do with the thyroid gland.

Clinical, Functional and Pathological Observations on Some Cases of Chronic Nephritis.—Dr. James P. O'Hare of Boston made this presentation. The reader said that one did not expect patients to linger long with this disease, nor to be observed for 3 or 4 years with zero renal function. He would present two cases. The first was a girl who at 9 years suffered scarlet fever. At 19 she had severe anemia, probably having had marked nephritis without recognition. At twenty-three she came to the hospital complaining of blurring of sight, headaches, drowsy spells. The eye grounds were negative, there was no retinal sclerosis. The urine showed no albumin or casts. Phthalein output was 12 instead of 60. Blood urea was 4 times the normal. The kidneys could not handle salts, water and nitrogen. The girl improved in hospital, but later returned, this time with definite cardiac hypertrophy, retinal sclerosis and hypertention. There was no evidence of active renal degeneration, although function was nearly minimum. A year later she caught cold, and came to the hospital with blurring of eyes, edema of face and sternum, considerable vascular changes, blood pressure 190 systolic, 120 diastolic. Phthalein output was zero. She again improved, but 8 months later came back. She went into coma with marked uraemia and acidosis. Injection of sodium bicarb. improved the acidosis. She was fairly well for five months. When she returned there was marked dyspnea, retinal hemorrhages with tortuous vessels. She developed nausea and vomiting, and died of pleurisy superimposed on pneumonia. The blood nitrogen rose to 120 mg before death. At autopsy the kidneys were the smallest ever seeen, and under the microscope there was no kidney substance left. She had probably had nephritis from 9 years of age to 27, when she died. However, for the last 10 years, the disease was vascular, outside of the kidneys. She lived a limited life, which allowed the small renal function to operate as long as possible. The other case was similar, though in an old man, a tramp who (contrary to the last patient) did everything that was bad for him and drank heavily. He was 62 years of age when first seen, and lasted, coming to hospital at intervals, for five years, with practically zero kidney function. At autopsy the kidneys were found to be very small, the rare glomeruli were infarcted. The blood nitrogen at death was 200 mg.

Dr. H. O. Mosenthal of Baytimore said that these cases were of extreme interest. One would not expect these cases to live as long as they did, and one should determine what factors had weight in the prognosis, so that the therapeutic side might be determined. Aside from heart complications it was hard to say how long the patient would last. The low renal function meant retention of renal excretory products. Renal insufficiency *per se* would not prevent the patient living for long periods. The inability to excrete solids was often compensated by polyuria. Nephritis was not only an excretory problem, one was dealing with some form of intoxication affecting the body as a whole, ending in protein destruction. This killed the nephritics before they died of retention and it was what produced the acidosis. The big problem was to treat the intoxication and take care of the kidney so that it would not be overcome.

Dr. Edward F. Wells of Chicago said that in the management of these cases it was well to be frank with the patient. The patient usually wanted to know what was the matter with him and what he could do to be saved. The patient was informed that many parts of the body were involved, and that the condition was accompanied by great risk, but that nevertheless it was possible to live with comparative physical comfort for some time. It would take a wise man to say how long these patients were to live. One saw very small outputs of urea for months at a time, and then on some sudden strain (as influenza) almost unbelievable amounts were passed. When the circulatory system was impaired the patient was told (in writing) to avoid exercise that produced shortness of breath. Whenever he found he had to sleep with extra pillows the physician should be notified. Very elementary physiology was used to explain his condition. It was explained that he had about 15 pounds of blood and 25 pounds of solid material, and that the balance was water. Nutrition entered the system in watery solution. For the heart to pump up the blood it had to pull a distance of four feet, but in lying down it got assistance of two or three inches. This made the patient willing to lie down for some weeks with great benefit. In edema the flow outward could be started by stimulating the lymphatics. A patient might live for 10-40 years and then die of some other cause than nephritis.

Dr. L. A. Conner of New York said that the aged did not have the same metabolic rate as the young and that the standards of blood urea and nitrogen were different in the young and the old.

Dr. F. Billings of Chicago said that in the older days before they had these finer tests, they used to base the prognosis upon the uremia. Some years ago there was an irregular practitioner in Washington, who became very rich and was called in consultation to legislators and politicians. He moved to Milwaukee and treated extremely severe cases, often successfully. His method was to starve the patient, merely feeding him on nuts.

Dr. L. D. Bulkley of New York said he had known a patient with albuminuria for forty-nine years. Personally he had suffered severe attacks of albuminuria as long ago as 1870. He could also show any number and kind of casts the meeting would want to see.

Dr. O'Hare in closing said it was surprising to see how patients could live many months with low renal function. Often, as Dr. Mosenthal said, death was due to other things, not essentially nephritic; that is, cardiac failure, vascular crises and infections. Often the cardiac complication caused death that one would expect from pure nephritis. One was unable to prognosticate the reserve force of the body in some people.

A Note on Tropical Sprue.—Dr. Edward J. Wood of

Wilmington, N. C., made this presentation, which was given with the intention of arousing interest in sprue in the United States. One case was seen in New Hampshire (a North Carolina man), one in Syracuse (a Porto Rican), one in an eastern hospital (a North Carolina man). The symptoms in sprue were typical in the mouth, the intestines, and the blood. The tongue was inflamed and pink, differing from the pellagra tongue. The sprue tongue was paler with cobblestone appearance. The disease could be differentiated by the tongue alone. The diarrhea was from midnight until 10 A. M. The stool, very large, was called by English workers "cow-pad stool." It was light, fatty and suggested pancreatic insufficiency. The blood picture showed an index above 1. Anemia was secondary and appeared like pernicious anemia. Many cases were, no doubt, called pernicious anemia. The cells showed marked variation in size, with poikilocytosis. No nucleated cells. The relation between these two diseases would have to be studied.

Dr. Douglas Vanderhoof of Richmond, Va., said that great credit was due to Dr. Wood for calling attention to tropical sprue in the United States. The diarrhea was characterized by absence of pain and tenesmus and blood. There were four diarrheas thus characterized: 1. Diarrhea of achylia gastrica, gastrogenous diarrhea. These were 90 per cent. of matutinal diarrheas. 2. Pancreatic diarrheas, due to pancreatic insufficiency. 3. Diarrheas of pellagra. 4. Sprue. The loss of weight, weakness, stomatitis and anemia in the latter made it difficult to distinguish it from pernicious anemia. However, in pernicious anemia the individual was sometimes well nourished. There was much confusion between pellagra and sprue. In pellagra there were often definite mental symptoms. In sprue one noted the saccharolytic stools. Sprue could occur in individuals who had never been to tropical countries.

Dr. J. H. Pratt of Boston said that the feces of these cases observed under the microscope appeared to be composed of almost entirely fat. Many of these cases were passing unrecognized, because little had been written on the subject.

Dr. Alvarez of San Francisco said that there was a great deal of sprue in San Francisco in people returning from the Orient. The stools differed from those of pancreatic lesions. The flora was different. Many patients improved and got well on meat diet, as this altered the bacteria of the stools. Feeding the patient on starch brought about return of the symptoms. Vaccine made from streptococci at the back of the tongue had cured some cases. The strawberry cure was a puzzle. Why should a man with diarrhea improve on being fed two or three boxes of strawberries? No reasonable explanation had been found.

Dr. E. Libman of New York said that he had seen a case of sprue five years ago in a patient who had never left New York. There was complete achylia, and reflex disturbance of the lower extremities. Ashford had read a paper on sprue in which he stated there might be lack of gastric secretion. Then Dr. Wood reported achylia gastrica or hypochylia in sprue. This showed the resemblance of sprue to pernicious anemia, but up to the present no case had been described of sprue with a color index above 1. Dr. Wood's findings were of importance, as there was great difficulty in distinguishing sprue from pernicious anemia. The symptomatology would appear to show close relationship. It was a mistaken idea to think that the symptoms in pernicious anemia were due to anemia. If one did a transfusion one could remove the symptoms due to anemia, sleeplessness, restlessness, nervousness, but one did not remove the tongue lesions, or the achylia gastrica, or spinal cord symptoms. Some toxin affected the tongue, gastrict tract, and spinal cord, which was untouched. Sprue attacked the gastrointestinal tract and tongue and changed the blood, but the index was not above 1. Spinal cord changes had not been described. If a toxin for sprue were found it would give a lead in the explanation of pernicious anemia. In the few cases seen one was struck by resemblance to pancreatic achylia. It would be interesting by means of the duodenal tube to find out the condition of the pancreatic ferments.

Dr. Graves of Galveston, Tex., said that he desired to emphasize that sprue was becoming endemic in this country. It was imported from South America and Africa. A few months ago he saw a child three years old, in Louisiana, who with sprue had epileptoid symptoms. Whether there was a connection he did not know.

Dr. Livingston of Jamestown, N. Y., said that in traveling to Porto Rico he met two travelers suffering from sprue. One was a government official, the other a lady, the wife of a friend of his. He became interested in the cases and prescribed the use of concentrated hydronaphthol taken internally as an antiseptic, to counteract the offensive stench of the feces. The government official refused to use this, as he said it burned his mouth. The lady used it with great advantage and finally recovered and was the picture of health. This antiseptic had no toxic properties whatever.

Dr. E. J. Wood in conclusion said that sprue often was superimposed on pellagra. He had not seen any remedy that was of any particular use. Sprue, like pernicious anemia, seemed to help itself. It would be interesting to know the result of studies on feces in pernicious anemia. In regard to the high color index mentioned by Dr. Libman, this was apt to be before death, and not early. The scraped beef diet, with hot water, and nothing else had been found helpful and had doubled the hemoglobin. It was unfortunate that cases of sprue occurred in remote places where laboratory investigations were impossible. Thus it was often difficult to differentiate them from pernicious anemia.

Unusual Tolerance, Especially in Women, to High Arterial Pressure.—Dr. David Riesman of Philadelphia read this paper. These cases, he said, presented a regular type of patient, usually an obese woman of middle age, the mother of many children, in whom the multiple gestations and the care of raising the family seemed to be a factor. The menopause was no doubt a factor. There were often no symptoms except slight ringing in the ears. Blood pressure was high but the arteries soft. Another type had accompanying nephritis, and had a bad prognosis. One type resembled the hyperthyroid syndrome, with nervousness, but the patients were not benefited with iodides. Often there were no alarming symptoms, but the patient should be watched. Three classes of symptoms should be watched for: (1) Angina pectoris; (2) apoplexy with hemiplegia; decompensation from myocardial strain. Much could be done by stopping heavy eating and ordering lacto-vegetarian diet; care of the bowels, for these patients were usually constipated; and freedom from worry.

Dr. Joseph Pratt of Boston said that these cases could be divided into three groups: (1) Vasomotor neuroses with no arteriosclerosis; (2) a moderate group with essential hypertension with localized arteriosclerosis; (3) arteriosclerosis general. It would be interesting to find out whether the moderate neuroses pass on to persistent high pressure. If McKenzie's advice were followed, the general practitioner would become a research worker in these cases.

Dr. H. S. Plummer of Rochester, Minn., said that he believed the syndrome was common among men of the same age. The fundamental thing in treatment was cutting down stress, nervous stimulation, muscular exercise, meat in food, as regards quantity not quality. The total food came very nearly equal to the amount of stress, no matter whether carbohydrates or proteins. In stress of the thyroid the gland was asked to furnish more than normal amount each day.

Dr. L. F. Bishop of New York said that he saw many of these obese patients. They had to be so treated that they could live longer with a fair degree of comfort. One great remedy was outdoor exercise. It was difficult to get these stout patients to do this. They preferred to stay in the house or the stores. Outdoor exercise was the best stimulant for heart, lungs, and kidneys, and tended to eliminate worry. In regard to diet, one good plan was to forbid eggs. This cut out most rich dishes and cut out a protein of doubtful freshness, as most eggs consumed had been in cold storage. A third point was attention to the gastrointestinal tract. Most of these people were laxative fiends and had intestinal irritation from abuse of laxatives.

Dr. Anders of Philadelphia said there was a form of myocardial insufficiency where the blood pressure was abnormally high. If the myocardium was

strengthened, the hypertension would fall. Many cases of hypertension were due to overeating with insufficient muscular exercise. The two great factors were proper restriction of fat-forming elements and systematic physical exercise, provided that the aorta be not involved, in which case one should advise exercise with caution.

Dr. RIESMAN said that he thought that McKenzie's plan of keeping complete records of every patient was a good one, so that if the man returned years after one could tell whether he originally had any indication of some condition which may have developed later. In regard to Dr. Plummer, he believed that his work on the thyroid stands alone. In regard to Dr. Bishop's views, he felt that one could accept any statement he made as to regulating hypertension. Also he thought that one was right in refusing city eggs to patients with either high or low pressure. In regard to exercise, there were periods in which rest was as beneficial as exercise. This had to be carefully worked out.

SECTION ON OBSTETRICS, GYNECOLOGY, AND ABDOMINAL SURGERY.

First Day—Wednesday, June 11.

DR. THOMAS J. WATKINS OF CHICAGO, CHAIRMAN.

Presidential Address.—Dr. THOMAS J. WATKINS of Chicago paid tribute to the hero members of the section who had made the supreme sacrifice over there. He spoke of the progress the specialty of gynecology had made in the past year, especially in the domain of plastic surgery, the treatment of cystocele, the repair of perineal lacerations, and of vesicovaginal fistula. He spoke of the importance of lacerations of the cervix in relation to gonorrhea. The work of such men as Hitschmann and Adler had been particularly notable. Displacements of the uterus were diminishing in importance, and we had learned that a crippled uterus should not be suspended. Our knowledge of the treatment of acute pelvic infections had been advanced, and now we dealt mostly with conditions left as surgical residuals. In short, the profession was proud of the accomplishments of abdominal surgery, and much of this was due to gynecology. Comparatively new subjects coming into the limelight were endrocrinology and radiology. It is true much poor pelvic and abdominal surgery was still being done, with disappointing results. Abdominal sections should have definte indications. Tinkering with the uterine adnexa was done much too loosely. Too often the pathology alone was the guide, rather than the individual problem presented by the patient, her age, social status, etc., which are more important indications. She should be kept under observation, moreover, until the cure was complete, especially if she were neurasthenic. Too little opportunity had been given to young surgeons, who should be provided with fellowship and assistantships in hospitals. As a rule hospital organization was deficient, some of the printed forms used for gynecological diagnosis being pernicious. A notable exception to this statement was the admirable system of Halsted at Johns Hopkins. He praised the group study of surgery which was carrying modern knowledge into the smaller communities. In contrast to this was the reprehensible practice of surgery by men insufficiently equipped; it was true that some of the responsibility for this rested elsewhere, part of it with the faculties of certain medical colleges.

Analysis of Fifty Cases of Uterine Bleeding from Causes Other Than Malignancy or Myoma Treated by Radium.—Dr. SAMUEL M. D. CLARK of New Orleans read this paper. He had found that an abdominal operation could be avoided in selected cases. This paper was made possible by the kindness of the Radium Institute of New Orleans. Group I consisted of five cases, which were not reported at this time. Group II were those cases of violent dysmenorrhea which had resisted all treatment. Typically they were the spinster type, with the menopause in sight, and still virgins, most of them neurotic. Often they had only about ten comfortable days a month, the rest of the time being taken up with the pre and post-menstrual storm. Everything had been tried in these cases, the endocrines, curettage, etc. Finally it became imperative to stop menstruation. He reported twelve such cases in the paper. Relief was obtained by stopping the flow, in one case without permanent suppression of the menses, but usually this was inevitable. The essayist believed that every known method should be tried before radium was used. Group III consisted of cases of so-called chronic metritis, the age limit running from 36 to 56. Often these women had had many children, the uterus was frequently in malposition, and bleeding was rebellious. Curettage was without avail; packing was sometimes necessary. In these cases the possibility of malignancy was first eliminated, and then radium was tried. He found that this was less of a trial on the nervous system than surgery, and wished strongly to emphasize this point, also that it was less dangerous. He reported 33 cases with one unsatisfactory result only, where the uterus had later to be removed. There was some discomfort for from 24 to 36 hours after the process, such as malaise, nausea, etc., but this was practically negligible. If radium had no other field in medicine than this its employment would still be warranted.

Treatment of Myoma Uteri with Radium.—Dr. JOHN G. CLARK of Philadelphia read this paper. He alluded to the paper just read, which coincided closely with his views. He deplored a blanket policy in using radium as, for example, when it was employed even on cases at the menopause, although this policy was lately abandoned. The first essential in using radium was a proper diagnosis, otherwise serious mistakes would occur. The selection of cases depended on whether they were causing hemorrhage or not, and the size. Difference of opinion existed about this latter point, but he took cases under the size of a three to four months' pregnancy. There were many objections to radiating a large tumor, as Dr. Noble had pointed out several years ago. Cases with complications, as pain, were not suitable, or when the fibroid was associated with inflammatory or other lesions. Three or four such cases had been tried with bad results, flare-ups had occurred, and in two cases operations had been necessary. The tumor then must be causing hemorrhage, and not merely pressure symptoms, for then reduction was slow. He thought that the alleged dangers of sarcoma following myectomy were largely mythical, although cancerous degeneration might occur. The disadvantages of the radium method were, first, nausea, which was not serious, and might be due to the morphinization preparatory to gas; and, second, pain, which should not occur. If it did, especially if it were associated with fever, it suggested that the wrong sort of case had been selected. If pain existed beforehand it negatived radiation. The third alleged disadvantage was the untoward effect of making the menopause come on a little more sharply and be a little more prolonged, but this was not serious. As to failures, he had had only eight in 137 cases. The effect on the ovaries was much less than on the uterus. In a well-chosen case of fibroid, radiation was the method of choice, because it was simple, almost free from danger, and was most effective in relieving permanently the symptoms and ultimately diminishing the size of the fibroid. It was the most valuable addition of the last two decades in the treatment of elective cases of myoma uteri. The treatment was standing the test of time so far as permanence of cure and freedom from sequelae, and marked a decided progress in the treatment of myoma uteri if conservatively applied.

Dr. H. C. BAILEY of New York said that in the application of radium to a malignant neoplasm of the uterus there were two distinct problems presented: (1) The application of the radium to the cancer in a sufficient quantity to cause a retrogression of the growth; (2) The application to the rest of the uterus in a correct amount. The first problem was rather easy on account of the usual location of the tumor; the result resembled myectomy somewhat, and the return of the tumor was just as certain; therefore, reapplications of the capsule were necessary. His experience was that it was seldom effective, and caused serious lesions. As to the second problem, very large amounts were required, even as large as one gram. While this would and did kill all cancer cells in its vicinity, it also affected the pelvic organs, and such things as endarteritis,

sclerosis, etc., occurred later. He thought that an operation might be preceded and possibly followed by the application of radium. He agreed that small fibroids might disappear, but not often a good-sized stump was left, which was unfortunate. Again, if the abdomen were not opened serious conditions which often complicated myoma might be overlooked. Deaver of Philadelphia said that these were present in 28½ per cent. of cases. He said that all large, pedunculated, or submucous fibroids, should certainly be operated on and this left only a small, free group in which radium might be tried, but only as a tentative measure. The mortality was practically negligible in these operations, being about 1½ per cent. In cases where bleeding was the only indication, radium had its best field. A thorough curettage should be done first, however, and all the scrapings examined; evidences of malignancy might be found in one small place only. Partially ripe ova in young girls might be so injured by radiation that later on abnormal birth occurred.

Dr. Ernest C. Samuels of New Orleans stated that he had treated the cases Dr. Samuel Clark had reported. No attempts were made to radiate large or rapidly growing tumors, or those not causing hemorrhage, these latter having been left to the surgeon. As to nausea and pain, the cessation of the use of morphine had eliminated 75 per cent. of these cases; gas also had been abandoned. The cases treated numbered 125, in one of these there was no effect and three came to operation. He thought that the menopause was no sharper than normal, slower if anything. He did not use the large doses that Dr. Bailey mentioned; after three ordinary doses the patient was told that radium was ineffective in her case, and treatment was discontinued.

Dr. Arthur H. Curtis of Chicago said that he had treated 229 cases; 46 of these had uterine cancer, and got palliative relief which in 14 instances was very marked; no malignant case had been cured. The hemorrhage and the discharge ceased, the cervix healed over, and the pain disappeared in several cases, but of course there was always a fatal result finally. In protecting the bladder and the rectum he inserted rubber dams, instead of gauze packing; this forced the parts farther away from the cancerous tissue, and prevented adhesive vaginitis. Operation should be done either in the first 24 hours after radiation, or else an interval of two or three weeks should elapse. In noncancerous cases he thought that radium had a great therapeutic value, indeed, in indicated cases we should always get cure. In medium-sized or small fibroids, or in hemorrhage of the menopause usually a satisfactory result was obtained with 1200 milligram hours, but on account of the frequency of "hot flushes" he used only 1000, or even smaller doses in idiopathic cases. Some of these latter came back. For about two months after radiation there was some bleeding, and sometimes there was a profuse watery discharge for three or even four months, but these symptoms always ceased. In intractable leucorrhea of cervical origin splendid results were obtained with radium.

Dr. Richardson of Baltimore said that he was rather pessimistic about the value of radium in these cases.

Dr. Leroy Broun of New York said that he had treated 1760 cases in the Woman's Hospital in New York in recent years; of these 90 showed necrotic changes, 25 calcareous degeneration, and 25 were associated with malignant disease of the fundus. In other words, 8 per cent. of all fibroid tumors had complications that would contraindicate radium. Also in 3 per cent. more there were complications in the ovaries, and in 7 per cent. more infective salpingitis was present. Hence the danger of radium—the difficulty in making clear-cut diagnoses.

Dr. John O. Polak of Brooklyn wished to know how clear-cut diagnoses could be made in these conditions if they had dispensed with morphine and gas. He said that he had treated 76 cases for hemorrhage with invariable success, and in only three cases was protracted treatment necessary.

Dr. Henry Schmitz of Chicago spoke of leucorrhea persisting for six, eight, or even twelve months after operation, and thought that big doses of radium were responsible. Radium, he said, labored under the disadvantage that it was asked to undertake cases abandoned by surgery as hopeless, so that in these cases even a palliation of the symptoms was a triumph.

Dr. Samuel M. D. Clark said in closing that they did not use morphine or gas any more for the application of the radium, but they did use it to facilitate diagnosis. In regard to the alleged frequency of complications of uterine myomata he said that perhaps his figures differed on account of the source of his material. In the far South uterine myoma seemed abundant, and were five times as common in negro women as in white. Eighty-five per cent. of these cases had adnexal complications, leaving thus only 15 per cent. suitable for radium. He would like to hear suggestions for controlling menstruation in young girls without suppression.

Dr. John G. Clark said that radium was not the ideal nor the invariable treatment, but that for a small number of cases we had in it an invaluable remedy. The radiologist had to guard against faulty diagnosis; he should not treat any and every case sent him, or radium would fall into ill repute. The patient should be told to expect nothing for six or possibly ten weeks; if the radiation were done immediately following her period it might be that she would have no more of them, although there might be a yellow, sticky discharge lasting from four to ten weeks. The use of radium was not a competitor to surgery, but took those cases on which the surgeon disliked to operate.

Dr. Goffe spoke of the distinguished men from all parts of the world present at the meeting and moved that they be received as guests of this section, and admitted to honorary fellowship in the American Medical Association. This was passed.

The Results in Over One Hundred Operations for Uterine Myoma (Operative Versus Roentgen-Ray Treatment).—Dr. Arthur Stein of New York read this paper. He said that surgery was still the most effective weapon at our disposal in treating uterine myomata. He quoted a case of a 20-year-old patient operated on and the cervix removed; later on two masses formed back of the stump. Another operation was done and they were found to be retroperitoneal; when removed they were found to be myomatous and undergoing sarcomatous degeneration; this showed that these myomata might have metastases, contrary to general belief. He cited instances of mistaken diagnoses and said that the aid of curettage was sometimes impossible for diagnosis. He did not believe that either radiation or *x*-ray treatment ever made tumors disappear. In his cases with various forms of myectomy he found single or double pyosalpinx in 26 cases, an adherent appendix in 18 cases, cystitis in 17 cases, ectopic gestation in one case, hydrosalpinx in 12 cases, adhesions in 8 cases, and gall stones in two cases. In other words, 50.8 per cent. of his cases had complications, which was a high incidence probably due to the class of cases he got at Harlem Hospital to which also he attributed his rather high mortality, 3.3 per cent. He came to the conclusion that treatment by the *x*-ray was not the method of choice for four reasons: (1) It was difficult to determine whether tumor was benign or malignant; (2) Complications occurred in half the cases; (3) The *x*-ray destroyed the function; (4) The *x*-ray had a deleterious effect on the intestinal mucosa.

Dr. G. E. Pfahler of Philadelphia said that he approved of a conservative attitude rather than the radical one expressed by Dr. Stein. He always accepted the diagnosis made by the gynecologist, and if a patient came to him without a diagnosis having been made he told her to have an examination. Referring to the pretended dangers of malignancy, he said that 7 to 10 per cent. of all these cases were supposed to be malignant, so that in the 150 cases he had treated he should have had from ten to fifteen malignancies, but he had had none. What had become of them, and also what had become of the malignancies in the 2000 or so cases reported in the literature?

Dr. Goffe of New York thought that operations were not getting their due, possibly because of the fearful mortality which formerly existed—that is, about 50 per cent. The same complications caused death in the operative cases as in the radium ones. He believed that an operation meant less difficulty, danger, and discomfort for the patient who went out of the hospital in from ten to fifteen days greatly relieved.

Dr. Joseph B. DeLee of Chicago raised the question of pregnancy after the use of radium. He was not sure that a woman could become pregnant after radiation.

Dr. Cullen of Baltimore said that malignancy in his experience was not nearly as high as 10 or 15 per cent. He thought that both radium and roentgen rays were useful aids to the surgeon, but that surgery was the thing.

Dr. Henry Schmitz of Chicago said he could answer Dr. DeLee's question, for he had a patient who was delivered nine months after radiation, and whose child was now five years old and healthy.

Dr. Peter B. Salatich of New Orleans said that one lost sight of the surgical cases, but not of the radium ones. He had a case where during operation an extraordinary friability was found, probably due to a previous radiation, and later a fistula formed. Radium should be restricted to nonoperative cases, as *e.g.* patients with bad hearts, or to tide a patient over until operation. He spoke of the mysterious etiology of myoma, and suggested syphilis.

Dr. Broun of New York spoke of sarcomatous changes in fibroids; at the Woman's Hospital in New York, in 1,760 cases, there were only seven of these, or less than three-tenths of a per cent.

Dr. Cowdin of Nashville, Tenn., contrasted operation with radiation.

Dr. Arthur Stein, in closing, said that sometimes the radiologist will pronounce a case cured, but the surgeon gets it later. We must improve our methods of diagnosis before we can be sure we have pure myomata.

Dr. Porter of Ft. Wayne, Ind., said that on the surgical side we had definite facts, and on the other we had only a vague and nebulous adumbra. Other things being equal, we should take out the fibroid and end the matter.

The following appointments were announced to the executive committee: Drs. C. J. Miller, J. O. Polak of Brooklyn, and H. P. Newman of San Diego, Cal.

Dr. Goffe alluded to the International Congress of Gynecologists and Obstetricians, the meetings of which had been interrupted by the war. Now that normal scientific relations with Europe were being resumed he suggested that an effort be made to reorganize that society and to that end proposed the following resolutions: (1) That the Section on Obstetrics, Gynecology, and Abdominal Surgery of the American Medical Association approve of the formation of such a congress. (2) That a committee be appointed by the chairman of the Section on Obstetrics, Gynecology, and Abdominal Surgery to affiliate with other committees in perfecting such an organization. (3) That the Congress of Gynecology and Obstetrics be extended a hearty invitation to hold their first meeting in the United States of America. (4) That the house of delegates be requested to approve these resolutions. The resolutions were unanimously passed.

The Teaching Function of the Hospital; With Especial Reference to Gynecology.—Dr. George Gray Ward, Jr., of New York, read this paper. He stated that hospitals were on the increase and that next in importance to their obvious functions were their possibilities as means of medical education. Every hospital was a mine of material—too often unquarried. It could be made of untold benefit to the community as a teaching center, and we should educate hospitals as to their duties and privileges in this regard. It had been the all too prevalent custom to drop a graduate into a hospital and let him sink or swim. We should carefully supervise his progress, see that he reads the literature, learns to take a proper history and encourage him to undertake some research problem. There should be a resident gynecologist immediately in charge of the training of these interns. The teaching of nurses was too perfunctory, standing orders multiplied, conflicted, and were too often merely ignored because no one had made it his business to harmonize them. Interns should be encouraged to progress into residents, attendings and members of the board; they should be given research work to do and offered every possible facility. Staff conferences were of the greatest importance, and should consist of pathological demonstrations, and of frank discussions of therapeutic failures and casualties. In short, it should be the duty of every attendant to a hospital to bring out to their utmost the potentialities latent in the young men under him, and to develop successors to himself and his colleagues.

Dr. R. M. Harbin of Georgia said that he had been visiting many hospitals lately, and had been particularly impressed by the difficulty in finding in any hospital a definite system of post-operative treatment. The minor points in hospitals were extremely important.

Dr. J. S. Stone of Washington, D. C., said that our aim should be to train and encourage the intern. We wanted members of our hospital staffs who should be qualified and our gauge was roughly such things as these: They should be members of the American College of Surgeons and producers of solid contributions to the literature of their specialties. He thought that the merging of the control of a hospital into the hands of one capable member of the staff would promote standardization.

Dr. John O. Polak of Brooklyn contrasted morbidity with mortality. The good we did depended on accurate diagnoses, and these were not possible when patients were brought into the hospital the night before a proposed operation. Follow-up systems should be established, as at the Long Island College Hospital, where the discharged patients returned at monthly intervals for a time and the results were studied.

Dr. J. L. Bubis of Cleveland, Ohio, said that the usual dispensary methods were wrong. Instead of so much care being taken to find out the service to which to send a patient she should go to all of them and have a complete diagnosis.

Dr. J. Henry Carstens of Detroit said that there were all kinds of hospitals and all kinds of standards. Often favoritism would enter into appointments. Private hospitals presented peculiar problems. Too much follow-up might make hypochondriacs and permanent invalids.

Dr. Ward, in closing, said that he thought that the crux of the whole thing was educating the trustees.

Alternating, Periodical Swellings of the Ovary.—Dr. Emil Ries of Chicago read this paper. He spoke of the puzzling tumors which appeared on one side of the uterus and suddenly vanished, only to reappear later, perhaps on the other side. Sometimes menstruation would be delayed two weeks, then appear and become profuse, and then the appearance of such a tumor would not unnaturally give rise to the diagnosis of ectopic pregnancy and sometimes an operation would be done. The diagnosis of scolecoiditis had even been made. These tumors were due to corpus luteum cysts. He described three cases he had observed for a period of years each. There was something about the corpus luteum not yet understood which caused such an anomalous condition and also perhaps the strange sclerocystic degeneration of the ovary.

SECTION ON NERVOUS AND MENTAL DISEASES.

First Day—Wednesday, June 11.

Dr. Archibald Church of Chicago, Chairman.

The Pathology of Cervical Ribs.—Dr. Archibald Church of Chicago, in this, the chairman's address, alluded to the very meager literature of this subject which was only adequately mentioned in the text-books by Oppenheim, yet their frequency exceeds all conception. They were found in about 4 per cent. of all skeletons. In regard to the disturbances caused by them, Dr. W. W. Keen published an article on this subject some years ago and Dr. L. L. Barker had made many interesting notes on his own person. They were surprisingly neglected by orthopedists. In Europe they knew the condition chiefly through the work of Gruber and it was called there by his name. He divided them into three classes: (1) Those which did not extend to the tip of the transverse process. (2) Those extending to the tip or slightly beyond. (3) Those more extensive. Other skeletal anomalies were usually present with these ribs, especially about the sternum; they were frequently associated with torticollis. They were often mistaken for aneurysm. These ribs might give rise to pressure symptoms in the arm and hand, especially if heavy weights were lifted often. Apical tuberculosis

was not uncommon as a concomitant. A sclerosis of the subclavian artery might give rise to symptoms by pressure on such a rib. They could not be identified by palpation alone; the *x*-ray was a very definite method of making the diagnosis, but even with this they could very easily escape notice if they were either very small or very large; in the former case they were overlooked, in the latter case mistaken for first ribs. Vascular changes were not so common as nervous ones. The pulse on the side of the extra rib was affected, especially if any weight were carried on that side; there were several instances of it in the army where the carrying a gun brought these symptoms which in time led to the discovery of the unsuspected rib. Vasomotor changes were found on one or both sides. The sensory defect was sometimes confined to one nerve. Radiating pains were observed, worse in ulnar fingers. Other symptoms which had been described by various observers were dissociation of sensation, all forms of "claw" hand, paralysis, rarely complete, trophic disorders, ptosis, pupillary changes, hoarseness, etc. Cervical ribs were so often associated with scoliosis of that part of the spine that they should always be suspected when the latter symptom is present. The operation was very difficult and no periosteum must be left. In every case of inexplicable pain about the shoulder or hand we should suspect the existence of these ribs. By elevating the elbow and putting the arm at rest we might get recovery.

The Mechanism of Referred Pain, Hyperalgesia, and Alcoholic Injections for the Relief of Neuralgia, with Suggestions for the Surgical Treatment of Injured Nerves.—Dr. Joseph Byrne of New York read this paper. He said that referred pain was a misnomer and really meant pain anywhere in a somatic path while pain occurring from visceral disease was reflected pain. He spoke of the theory of pain, of the two sets of fibers, the affective and the critical. The factors responsible for pain resided in the dorsal ganglia, hence severing a nerve far away from one of these did not relieve the pain. He said that 80 per cent. alcohol was too strong for injection into a nerve; that it should be 60 per cent. and then be injected into the sheath. He studied the changes in the proximal part of a severed nerve and found that it sent out many little axonites with bulb ends which later functioned and overfunctioned. Hence it was very important to sew up a nerve at once. There was no pain for 14 days, while the nerve was trying to unite, then hyperalgesia occurred.

A New Polyglandular Compensatory Syndrome.—Dr. Walter Timme of New York read this paper. He said that for several years a group of patients were noted in his clinic with similar symptoms which were finally formulated as follows: Intense intratemporal headache, easy fatigability, low blood pressure and blood-sugar as low as .060 of 1 per cent. Under the *x*-ray a closing-in of the sella turcica and a persistence of the thymus were found. Their histories were also similar: Before puberty, eneuresis, fatigability, dullness and spasmophilic and hemophilic tendencies. He quoted several illustrative cases, some having come from the Draft Board or the army where their great height had brought discredit on their history of fatigability. The etiology and pathology worked out by Dr. Timme were these: Adrenal trouble originally, compensatory activity of the pituitary, hollowing out of the sella turcia to accommodate it which, if successful, leads to a more or less complete self-cure, if not successful, must be helped by pituitary feeding.

Dr. Tom A. Williams of Washington called attention to some of these cases lacking one or more symptoms, but said that the severe bitemporal headache was the symptom *par excellence*. He suggested that when there was no response to organotherapy we might try to reduce the hypophysis cerebri by the roentgen rays.

Dr. Charles E. Sterne of Indianapolis spoke of the antagonism of the anterior and posterior lobes of the pituitary and thought these cases should be divided for treatment into pre- and post-adolescent states. He got better results by hypodermic administration and found the anterior extract harmless.

Dr. Timme said he thought that anterior extract was very harmful, causing nevi, enlarged cervical glands, etc., if not carefully controlled. He saw no advantage in the hypodermic method of administration.

Dr. Hugh T. Patrick of Chicago spoke for the editorial board of the Archives of Neurology and Psychiatry, stating that they would like good, constructive criticism.

Dr. Tom A. Williams of Washington moved that a short time after opening on the following day be devoted to discussing the magazine; this was amended by adding an expression of confidence in the present editors, and carried.

Dr. Theodore H. Weisenburg of Philadelphia thanked the society and stated that the editors welcomed criticism and help at all times.

Treatment of War Neurosis.—Dr. Theodore H. Weisenburg of Philadelphia read this paper. He stated that Dr. Schwab in a recent paper had described the neuroses seen in France so fully that he would only discuss those he had seen in Plattsburg. One peculiar symptom seen in one case was a tremor of the eyeball, psychic in origin. Many difficulties in diagnosis were encountered, especially in the epilepsies. He thinks there is practically no difference between the neuroses of war and peace, differing from Schwab. The armistice made this difference, that following it symptoms could hardly be suggested, but patients took kindly to ideas of recovery. There were no "miraculous cures," however. Treatment was not difficult and often surprisingly rapid and successful.

The Management of War Hysteria.—Dr. Tom A. Williams of Washington read this paper, which was based on a very intensive 18 months' study in France. Simple persuasion was used by the French while he used a subtler psychotherapy. He believes that neuroses of peace are the same as those of war and have as good a prognosis, provided we can get some sort of control over them. He suggested that litigants be compelled to take expert treatment under penalty of forfeiting all claims. Torpiage was only used in France by one man on account of public sentiment against it, but he had had great success with it. Reeducation was the only method offering intelligent, permanent results. Pains were very difficult to cure.

Dr. Robert MacGregor of Saginaw, Mich., alluded to cases seen in England and France and said that the victim of shell-shock was always a potential epileptic.

Dr. C. A. Rosewater of Newark, N. J., quoted a paralysis of ten years' standing cured at Plattsburg by intelligent, individual psychotherapy.

Dr. Hicks of New Jersey wanted to know how the real psychoneurotic could be distinguished from a clever and persistent malingerer.

Dr. Pollock of Chicago saw many cases in France and very few had neuropathic taint in heredity. He saw very few reflex neuroses in wounds of the extremities but thinks that these may be found in the future.

Dr. Weisenburg in closing said the differentiation of malingering and psychoneuroses was often difficult, sometimes, perhaps, impossible.

Dr. Williams in closing said the diagnosis of malingering depended upon contingent symptoms, not upon clinical tests. Fear is not always the mechanism in war neuroses. Anxiety cases must be carefully sorted out and never treated as the others.

The Psychopathology of Amnesia.—Dr. Edward E. Mayer of Pittsburgh read this paper by title only on account of limited time, but quoted briefly three cases of amnesia, in each of which the patient had thereby gotten out of an extremely difficult situation. In these cases it was impossible to tell genuineness of the symptoms shown.

Dr. Joseph Byrne of New York said the trouble with psychotherapy was that we could not state its principles and hence stood on the same level—in the public's eye—with the chiropractor and the naturopath.

Dr. H. Douglas Singer said that too much stress was laid on the question of responsibility, which was beside the point from a medical standpoint.

Dr. Jones of Minneapolis spoke of the physical side of amnesia and said that all amnesics who had no physical lesion were malingerers.

Dr. Tom A. Williams of Washington pointed out a connection between the war and occupation neuroses and said that many originate in a lowered physical potentiality; this persists and becomes hysteric.

Dr. Mayer in closing said that while we might dismiss the question of responsibility in a medical meeting, in the law courts we had to answer.

RADIUM, ITS PRESENT STATUS AS SURGERY'S ADJUNCT.*

By C. EVERETT FIELD, M.D.,

NEW YORK.

DIRECTOR, RADIUM INSTITUTE.

THE title of the paper covers the ground of the relationship of radium activities in surgical methods. This is a very broad and extensive proposition, because it takes in morbid conditions of the human body wherever surgical interference of any kind may be indicated, as, for example, in diseases of the bone, of the blood, and in any chronic or acute inflammatory condition in which curative effects of radium have been recorded.

An interesting but an infrequently discussed subject, which offers a large opportunity for instructive work, is the action of radium applications in diseased sinuses of bone and in the soft tissues of the body, such as follow infection from deep and extensive injuries; as for instance, in the fistulæ and sinuses remaining from gunshot or shrapnel wounds.

We will confine this paper to the treatment of malignant tumors. In the light of experience, from both a clinical and a practical viewpoint, the action of radium as an aid to surgery may be classified for purposes of discussion into four divisions, as follows: First, as a substitute for surgery; second, before surgical proceedings as a preparatory method; third, combined with surgical procedures; and fourth, postoperative or prophylactic use. In the first group are all lesions which are inoperable or ineradicable by any surgical implement or method, whether the knife, scissors, cautery, caustics, or other well known surgical means of enucleation. In all inoperable malignant conditions or when the growth is ineradicable radium is indicated. Radium is indicated when surgery is impracticable or impossible, because of inaccessibility of the growth, its extent, its special nature, the malcondition of the patient from a prolonged duration of the disease, or in cases where excessive mutilation or impairment of normal functions would follow a proper removal. Example: A tumor located in the liver could hardly be removed with any hope of safety to the patient or promise of a cure for the disease.

Malignancy involving not only the uterus and adnexa, but the adjoining lymphatics and neighboring structures, offers no hope of cure by any ordinary surgical method of removal. Epitheliomata of the ear or the eyelid, of the entire lip, or the nose are presumably inoperable for cosmetic as well as physiological reasons. Cancers of the tongue are now regarded by most surgeons as inoperable, at least the promise of cure is almost worthless. Their rapid return after complete excision is so certain as to discourage all but the very young and very bold operator. So much is this true, according to modern surgical experience, that radium becomes the remedy of election.

There is a class of cases where surgical interference seems to hasten the death of the victim, even when the disease to all appearances has been radically and widely removed. Apparently the operation stimulates the growth and recurrence of the neoplasm. Melanosarcoma is such an example. In these patients excision, no matter how extensive, how wide of the tumor, and how well carried out, appears to stimulate the growth and insure its rapid return. The only hope of a cure in these patients lies in the use of radium and not in the knife.

There are three specific diseases where the reports of relief by the use of radium are so definite and certain and are confirmed by so many cases, as well as by the experiences of such a number of observers of unquestioned veracity and skill, that radium is, from the first, the method of choice.

The diseases referred to are lymphosarcoma, tuberculous glands, and fibroids of the uterus. Lymphosarcoma usually occurs in the neck, the mediastinum, and the retroperitoneal regions. The lymphosarcomata are not very amenable to local attack, that is, removal by any surgical proceeding is difficult and doubtful because of their diffuse occurrence and their inaccessible location. As a rule, before these tumors present at the surface of the body they are already infiltrating widely from the situation where they originally appeared. This particular variety of sarcoma arises in the connective tissue wherever lymphoid tissue abounds, particularly in the mediastinum and in the retroperitoneal tissue. The distinguishing features of this tumor are its infiltrating propensity, its lack of a limiting capsule, its non-limitation to any single organ or structure, and its inherent tendency to invade other organs. The very first principle of proper surgical treatment of neoplasms is a complete and wide excision of the growth. In this class of growths proper operative treatment is impossible. Fortunately, these frequently occurring and rapidly fatal tumors of young adults are often quickly responsive to radium. While the disease can be said to be almost immune to treatment by the knife, reports of the brilliant results from ra-

*Read by invitation before the Ex-Internes Society of the Methodist Hospital, Brooklyn, N. Y., February, 1919.

dium treatment on these neoplastic growths come from Kelly and Burnham, Tally, Linther, Dawson Turner, Holding, H. Smith, Janeway, Burrows and Cullen, and others.

Fibroids of the uterus are tumors clinically approaching malignancy in many ways. Removal of these growths is an operation of ordinary simplicity to the skilful surgeon and quite attractive in its immediate results. A satisfactory result does not always follow even the best surgical efforts. Surgery, however carefully and completely performed, may incapacitate the uterus. Operation does not always remove all the growths and the uterus itself may have to be extirpated, the patient being thereby made sterile. Not infrequently operative sequence, even in successful cases, leaves a useless organ, while a fatal issue is the occasional result after this major operation. On the other hand, remarkable results have been recorded in operable and in inoperable uterine myomata through the use of radium. At the Radium Institute, in three years, we have treated sixty-two cases of uterine fibroid with over ninety per cent. favorable results. Kelly and Burnham, Abbe, Clark, Wickham and Degrais, Cheron, and many other well-known gynecologists and radium therapists have reported several hundred cases where radium applications have produced certain and uniform reduction in size of the fibroid until it disappears completely or is diminished to a very small and negligible growth. It seems that this brilliant cure of a pathological condition, previously amenable only to the knife and not always then with satisfactory results, justifies all the time, study, expense and any sacrifice of human effort spent to bring radium into the surgical armamentarium and qualifies it as a definite therapeutic agent.

The atrocious destruction of youthful male life that has resulted in the great war of the old continent creates a demand for an increased birth rate. The restoration of this important child-bearing organ to its normal reproductive state without mutilation or impairment of function must have a very important bearing upon the political economy of the world. The ability thus to restore to society a large number of child-bearing units, of which otherwise the State would be forever deprived, might be considered an accomplishment of great scientific and economic value.

The position of radium therapy as relating to tuberculous glands is certainly unique. The uniformly good results that have followed the use of radium, especially on glands of the neck, lead us to class it practically as a specific. If such a statement is to be accepted we can scarcely justify surgical measures.

In the second class, radium is advised as a preparatory treatment; here opinions are divided. Many operators advocate strongly the avoidance of any interference with the affected tissue by radium application before operation, contending that such treatment destroys much of the recuperative quality of the neighboring structures and lessens the local vitality, and also that it interferes with the absorbing power of the tissues and affects adversely the general condition of the patient. On the other hand, many observers assert that inoperable cancers may become operable by proper radiumization. Nogier, of Lyons, advises repeated radiation of the lymphatics of the growth at the circumference of the tumor. He proposes destroying the malignant cells and blocking off the communicating and distributing vessels. This prevents the carrying of those cells away to form metastases. Such radiation is to be begun at the peripheral end of the lympatics. The results of our experiments with the microscopic examination of radiumized tissue strongly support this premise. I heartily sanction preoperative radiation when instituted and terminated at least ten days prior to surgical treatment.

Souligoux of Paris asserts that preoperative radiation kills the outlying cancer cells and thus helps the surgeon in his efforts at the total extirpation of the disease. Other operators believe that this form of treatment reduces the size, extent, and fixation of the growth and renders total extirpation easier and more certain. Opposite opinions are that radiumization congests the tissues and by causing the formation of excessive fibrous tissue in the broken-down structures produces adhesions and makes the operation more difficult and less promising. In one case of cancer of the cervix, reported by Burrows of Manchester, the fibrosis was so great that the operation undertaken after preliminary radiumization had to be given up, although in five similar cases radiation had been administered and extirpation was satisfactorily performed. Personally the author has witnessed no bad results in 132 preoperative cases, yet has refrained from generally advising preoperative radiation owing to the lack of more extensive trustworthy data. At times the surgeon is confronted with pathological conditions involving the uterus complicated by severe and prolonged hemorrhage. Indeed, we frequently see cases where the condition is so serious as to prevent all thought of performing the operation that seems surely indicated. In such a situation we urge the intrauterine and suprapubic application of heavy radiation. The happy results that usually follow this procedure win many lasting friends for radium therapy. In the large majority of such cases hemorrhage is promptly checked and the patient is soon prepared for the necessary operation.

In the third group are the cases in which radium application and surgery are combined. This divides itself naturally into two classes. First, those cases in which it is impossible to remove all the cancer tissue and it is desirous to employ radium in combination with surgery to obtain the effect during operation and after the time of the operation. To do this, immediately on finishing the excision an adequate amount of radium is packed into the wound cavity before closing. This is allowed to remain the required period of time, after which the sutures are drawn in to bring the wound together. Second, where a large cancer mass is to be removed in order to shorten the time of treatment with radiumization, and cases where the operation is simply to avoid the necessity of absorbing a large amount of broken down cancer cells and toxins which otherwise must necessarily be carried off by the physiological processes of the body. In this subdivision the operation is performed in order to facilitate the use and effect of

the radium. Surgery is employed here to assist the action of radium. No operation for a neoplasm is satisfactory which does not remove the most widely spread cancer tissue. In sarcomata, especially, is a wide sweep of the excision line indicated, and the operator is never quite sure that it is wide enough. Radium, at the time of excision, would add to the probability of a more thorough and extensive destruction of the suspected tissue without dangerous mutilation. Theoretically this is an argument for the use of radium in all operations, for in no case can it be certain that the knife has extirpated the furthest cancer nests. In the removal of a cervical carcinoma, for instance, infiltration into the broad ligaments and vagina seems to call for radium at the time of the operation and several hours thereafter.

In the fourth group we have postoperative prophylaxis. Of the necessity and the values of this method there can be no doubt and yet many well known gynecologists, as well as skilful and experienced general surgeons, still maintain a lukewarm attitude toward radium. There have been so many sensational claims made for radium in its earlier day that we may excuse their skepticism. During the past two years, however, many of the foremost surgeons have accepted postoperative radiation without criticism. In fact, it is becoming a routine measure with some gynecologists.

Repeatedly, in the experience of the writer, under carefully carried out radiations, malignant recurrences have disappeared. Nodules have been destroyed and ulcerations checked. Hemorrhages have ceased and, perhaps because of the mental benefits produced, the general condition has greatly improved and the patient has been clinically restored to health. If this is true why not systematically make one or more prophylactic applications of radium in every case to the involved area at the location from which the cancer mass was totally removed as well as to the surrounding tissues where recurrences might be assumed to present?

There is always something to be said about those cases where operation is impossible or where recurrence is rapid and overwhelming in its return. Such victims of malignant disease are not infrequent, and for them there is no other chance, no other resource, except that which may be granted by vigorous, massive, and long-continued doses of radium. It holds out for them at least some relief of pain, hemorrhage, odor, discharge, and other inconveniences or distress, and if applied with confidence and belief in its efficiency, in adequate amounts, by an expert of acknowledged skill, it may help them both physically and mentally and restore, if only temporarily, the joy of life and hope. We have not done all for such a patient unless this final means of healing is tried.

205 West Seventieth Street.

Liability for Ship Surgeon's Negligence.—A ship is liable for the incompetency and unskilfulness of its physician and surgeon in the treatment of an injured passenger only when it has failed to exercise reasonable care in employing him. The Circuit Court of Appeals, Ninth Circuit, holds that the failure of a ship's surgeon to treat an injured passenger and the treatment of another for a contused wound, when there was a compound fracture of a bone of her leg, was negligence for which the ship was liable.—The Korea Maru, 254 Fed. 397.

FIBROMYOSITIS OR "RHEUMATIC CONDITIONS."

By J. Madison Taylor, A.B., M.D.,

Philadelphia, Pa.

Professor of Applied Therapeutics, Temple University, Medical Department.

Long observation convinces me that one of the largest contributions any one is capable of making to medical potential, is by reducing to simple factors, common denominators, and methods of relief, that constant thorn in the side of the profession, muscle pains, fibromyositis, or so called rheumatic states. Probably there is nothing in the clinical category so fertile of blunders to the medical man, nor so fruitful of resources and income to the extra mural healers.

Whatever simplifies our clinical concepts aids to amplify relief measures, provided pathological consistency be not sacrificed. A working basis or common denominator is needed, capable of explaining the phenomena of those variegated and constantly recurring sensory derangements characterized by local sensitiveness, rigidity, tonic protective spasm, muscular hypertonus, and the manifold associated distresses or puzzling transferred pains. Let us visualize this group of sensory disorders under one graphic term—fibromyositis—which well describes those miseries called by the misleading term "rheumatic," myalgic, oxypathic, arthritic, lithemic, and the like.

Along with these closely associated or concurrent muscle sicknesses (myopathic or myogenic phenomena) there occur disturbances of the gross reflexes, among which are spasm, contracture, tenderness, dermal and subdermal "soreness," flatulence, sometimes tremor, and multitudinous vasomotor imbalances.

Many other system disturbances are likewise encountered as correlates or resultants of these sensoripathies, such as those of innervation, of respiration, of circulation, of digestion, or genitourination, also morphologic deformations, lamenesses, and also a diversified group of psychoneuroses or disorders of personality. These psychophysical bewilderments deserve attention from a common etiological source, or point of departure, as well as from shocks produced upon or within their special mechanisms and regulative agencies.

The uniform point of departure is presumably one of disordered biochemistry, of metabolism (or impaired catabolism) usually of the governing or regulative mechanisms, hypo- or hyper-function of the ductless glands.

The question naturally arises here: Why are some individuals readily subject to fibromyositis and others not? This has not been answered satisfactorily as yet, so far as my survey of the evidence tells me. I offer a fair ground for surmise, however, to the effect that these variants in myopathic (or fibromyopathic) susceptibility are to be found in those, as yet obscure, conjectural realms of divergences in "types of tissue soils" which are now receiving attention. Among the more recent and graphic types brought to notice by the war is neurocirculatory asthenia, lowered shock values, or "delicately poised organizations," so called "nervousness." Here we are

on the verge of a new incarnation of an old acquaintance "diathesis" or "dyscrasia," and there we may safely leave it and proceed to the practical subject engaging attention.

One of the most common, disabling, and often distressing of chronic or protracted disorders is the so-called "rheumatic state," myopathy, or myositis, better named fibromyositis. This clinical entity often forms the basis, or clinical background, for an enormous variety of morbid phenomena, physical and mental. The condition is not always painful, nor even tender, but is capable on aggravation of exploding into torture and mental confusion. It obscures the clinical issue so often as to act as a serious peril.

Among the distresses or disabilities referable to fibromyositis are: Headaches, backaches, lamenesses, diverse intraarticular stresses, restrictions of movement (often not recognized as pain states), contractures, deformations, faulty attitudes, and psychogenic as well as morphogenic confusions, along with intestinal inflammations, even appendicitis. Any one of these may follow, seeming to be the effects of acute disorders of varied origins. Referred pains, while due to particular causes, are many times aggravated by fibromyositis. Sometimes there are osteophytic proliferations with decalcification of vertebræ, but even then biokinetic treatment can effect cure.

The means of restitution lie in two chief directions: dietetic or metabolic regulation, and the resources of reconstructive (biokinetic) measures. Of these, the latter are most prolific of relief and the former for removing the underlying causes and staying progress. Indeed, if the condition has progressed far enough there is only one means of radical emancipation, viz., by revision of conduct through reconstructive personal hygiene, including education of the skin and muscles. My experience leads me to believe that without a thorough marshalling of reconstructive, especially manipulative, measures, rheumatic states will persist or recur. Sometimes counter irritation is necessary—local freezing is best, strong iodine or cantharides covered by zinc oxide plaster. The colon should be irrigated with water, better four or six gallons by a two way tube, in and out and in and out again, till the whole gut is clean; this should be repeated every other day for two weeks. Salt (NaCl) and sodium carbonate, purified, may be added with advantage.

So prevalent a condition deserves attention for the reason that in spite of its universality it too often escapes recognition; many contradictory conceptions obtain as to its nature; many errors as to its phenomena, progress, significance; also as to the most economic means for relief and cure.

Let me here urge attention to the need for determining whether any obscure tenderness or pain on movement or recurrent or shifting pain be fibromyositic in character, no matter what other recognizable or reasonably inferential cause coexists.

Diagnosis, obscure in many definite clinical entities, frequently reveals the coexistence of a fibromyositis. Whether the derangements exhibited be sensory, static, or inflammatory, no treatment for the overshadowing disorder will be successful until the accompanying fibromyositic process is dealt with *as a common factor proceeding from similar sources of origin and contributing to the distress or disability.* Tuberculous lesions often exhibit reflex or spastic muscle densities, as pointed out by Pottenger. These are, in my opinion, fibromyositic in character. So of all sorts of lamenesses, whatsoever other conditions also be present.

A fibromyositis is often the essential process when symptoms point reasonably toward more serious diseases or disorders.

A fibromyositis may be acute, and when prolonged may be accompanied by moderate febrile reaction, so large and complex are the sources or origins. It is then obvious enough, as in a sharp attack of myalgia of the lumbar muscles, the scapulars, the pectorals, muscles of the scalp, neck, and the like. The frequently recurring tenderness of the erector spinæ muscles, indicating irritation in the rami, are, in my opinion, of the nature of fibromyositis. To be sure, they point to irritations in the spinal subcenters and these must be relieved in order to cure associated miseries or diseases. Also there are often intraarticular irritations involving the arthrodial or amphiarthrodial structures, costocentric, between the discs or at rib junctures.

Fortunately manipulative treatments work both ways; not only by dissipating the local tenderness but also by reflexly stimulating vasomotor activities in the subcenters and thereby contributing to the nutrition in the disordered peripheral locality. Likewise mobilizations of the vertebræ, the intervertebræ, costocentral, vertebrocostal, and vertebrosternal junctures often contribute to restoration of function.

We should differentiate between neuralgia and myalgia. In neuralgia painful points are found in the nerve, at the outlet or in continuity—where nerves emerge from bone especially. After being relieved there is no further immediate tenderness in myalgia; in neuritis there usually is.

In myalgia pain is located in the body of the muscle, especially at its thinnest part, where most expanded, and is always distributed over a larger area than is that of neuralgia; tenderness persists over inflamed nerves between attacks. A zone of hyperesthesia or hyperalgesia exists which does not parallel the nerves. Myalgic points or areas correspond to where muscle blends into fibrous structure or tendon. Myalgia often simulates angina pectoris (Peritz), acute gastritis, especially when the belly is distended with gas. Also it simulates cholecystitis, appendicitis, sacroiliac disorder. A "sciatica" is often triumphantly detected, which in reality consists of fibromyositis in the muscles of the gluteal region, especially of the brim of the pelvis; also of the small lumbar attachments. Many lamenesses arise in muscle tenderness in the gluteal muscles and fibrous attachments to be detected only by expert finger explorations; they are curable readily enough by persistent manipulation.

Indurations, infiltrations, thickenings are exhibited, giving evidence of chronic myositis at points of lodgment. Certain stages are shown: (1) swelling, elasticity, sometimes glossiness of skin. (2)

bogginess, edema, a doughy feeling; (3) densities, rigidities, spasm, passing with age into ligament-like cords, which are tender to touch. These cord-like, stringy structures are characteristic of fibromyositis. They also are evidences of disturbed states (reflex spasm from a peripheral lesion) in paravertebral structures.

In late maturity certain muscle fibers are replaced by connective tissue and in these tendernesses are common, due to compressions of sensory nerve terminals when movements, active or passive, are made. The two earlier stages are most sensitive. They likewise come and go; *i. e.*, are less or more severe, but rarely absent at some time so long as the condition persists.

In older forms of fibromyositis with passive tenderness as well as active sensitiveness, the organism becomes so adjusted that the sensory responsiveness sinks below the threshold of consciousness; hence is operative in causing vague, unidentified distress, weariness, sleeplessness, aching, infirmity, atrophy, decrepitude, and mental depression or confusion. The origin of a deep seated psychopathy may often be found by tactile exploration as a muscle tenderness.

There may be no active sensory response; the awareness may be subordinated and brought out only by carefully directed tactile explorations, or by movements active or passive, and especially when fatigue or exhaustion coexists.

Favorite seats of myositic thickenings are the head (scalp), neck, in and about the knee, hip (sciatic area), shoulder and ankles, wherever muscles overlap; inside the elbow; insertion of the pectoralis major, of the latissimus dorsi into the humerus, the intercostals, of the abdominal wall, the crest of the ilia, the glutei or the gemelli. Indeed, the buttocks are a fertile ground for fibromyositic complexities variously named, generally hindering locomotion.

The diagnosis of latent forms of fibromyositis is largely by expert tactile apperception (an educated finger tip). The relief and cure, as said, lie in two directions, digestive (metabolic) regulation and the varied resources of reconstructive measures. Especially useful are heat, pressure, manipulation, separation of fibers by hand, or counterirritation by blistering or cautery.

Indeed if the condition has lasted long, and complications have progressed far enough, there is only one reliable means of emancipation, viz., through the resources of revised conduct, personal hygiene, improving habits, notably by attention to skin, and muscle training, passive and active. Never omit thorough bowel washings.

The point I wish to emphasize here is that whatever be the pathological process underlying most protracted or subacute maladies there frequently coexist forms and degrees of a complicating fibromyositis producing distress or disablement or both, and this demands relief *per se* When once the fact becomes realized and the main diagnosis is correct, but there is superadded another cause for the pain or disability and the clinician devotes his attention equally to both, then his duty to the patient is by way of fulfillment.

As a graphic example a vigorous young man consulted me for what he said his physician, an admirable exponent of the best ability, told him was a pleurisy which at any moment might grow worse and that it was dangerous for him to work. The man, feeling absolutely well except for a pain on taking a long breath, and sadly needing to earn money to live, determined to seek other advice. There certainly was no pleurisy, and there certainly was a point of fibromyositis along a rib, and a local tenderness. This I promptly dissipated. He could then breathe with no pain and returned to work immediately. Had this been neglected for some months the condition would have proved recalcitrant and obstinate.

Another was a master-mason whom the foreman on some repairs on my house wished to work on the job. This man rested under the medical ban of a subacute appendicitis for ten months. This proved to be merely fibromyositis of the rectus abdominalis and disappeared over night under counterirritation and strapping. He did his full work from that moment.

The most puzzling problems are those in which an obvious fibromyositis refuses to be cured, although much relieved, and other obscure phenomena persist. In most such instances there may be assumed a chronic irritation in the cell bodies of the cord from which the vasomotor nerves arise which supply the distressed part. The form is often a protective tonic spasm, usually detectable as a cord-like mass. When it is duly located, and after due attention is directed to the subcenter, one may effect a permanent cure, *e. g.*, by freezing the area two or three times, or by exerting some powerful mechanical stimulus to the part whereby adhesions are freed and the nerve outlets (gray rami) resume their functions unhindered.

Of the many forms of reliable treatment some are described later. In any event some expert (really expert) manipulation serves as an efficacious, almost necessary, adjunct. The main object is to relax the tension (protective spasm) in the affected structure, to diffuse the local stagnation, and stretch the muscle fibers from center to affected locality.

In most instances manipulation should be applied as nearly as possible to the origin of the muscle, where the main nerve enters the mass, not neglecting the belly or mid-portion nor the insertion.

Hand treatment should aim to empty the spastic muscle of vitiated lymph and blood; should be applied not too long at a time—two or three minutes with intervals to let the patient rest from the pain induced, and then repeat two or three times; total five or eight minutes. They should be again done on the same day or on successive days, being guided by the degree of "soreness" produced.

In the case of tonic muscle spasm often large sudden movements forcing the part first in one direction, then quickly back again, will throw a long disused part first out of its false position, then back into a normal one. This often overcomes the chronic spasm. It is by such means that the miracles of "replacement" of the bone setters are produced.

In the chronic and obdurate forms treatment should be repeated at least twice a week, gradually increasing the force and depth of pressure,

and length of séance. Manipulation should always be followed by active movements made by the patient, and by carefully directed functional training to secure accuracy in action and to equalize the coordination. Movements should be made in accord with laws of "protective reactions" and "distributing the direction of the load"; with due consideration to states of contracture or relaxation—tonus or hypertonus, also intraarticular pressure or irritation which I have described elsewhere.

A particularly important accessory measure is expert muscle training in exact directions and degrees of force. By this means confidence is restored as well as adhesions and contractures overcome. It is common to meet sufferers who have been admonished to make no movement which causes pain. The truth is *when a movement causes pain that movement should be made repeatedly with increasing force.*

The skin should be educated to protect itself and the hypersensitive muscles from chilling by friction with a dry towel on rising and on going to bed; also by gradations of exposure to air and by alternations of heat and cold, as by hot and cold douches. Dry skin friction is vastly superior as a tonic to the peripheral circulation than is bathing in any form. The late Weir Mitchell frequently used a "salt towel," *i. e.*, a coarse "kitchen towel" dipped in salt water and dried, for friction.

Summary.—1. Keep in mind that any obscure muscle pain, brief or protracted, or lameness, or morbid alteration of posture, or gait, or restriction of posture or movement, or tenderness, may be due to fibromyositis; hence determine by critical palpation what the afflicted or suspicious areas may reveal.

2. Relief of these local disordered conditions, whether painful, tender, or structurally significant, may clear up the matter; or in any event simplify the problem.

3. Cure of a fibromyositis may contribute materially to the limitation of any existing collateral disorder or "transferred pain" by the removal of sources of reflex irritation or "protective spasm," or by reducing the sum total of morbid factors present.

4. Local hypersensitiveness in muscle masses, due to any one of a large variety of primary or secondary causes, frequently is exhibited in the form of a fibromyositis, revealing other coexisting factors, such as a focal sepsis, a central irritation, or a peripheral diseased state.

5. Cure of the local manifestation may be achieved by revising and regulating conduct through personal hygiene, by modifications of diet, regulating exertion, reducing fatigue, especially exhaustion from excessive repetitions of monotonous motions as caused by restricted acts in labor; by accustoming the patient to abrupt exposures to temperature changes and by generally equalizing expenditures of force through salutary modifications in habits in accord with rational demands for activities.

6. In treatment, whatever other curative agencies are employed, don't omit to consider thorough colon irrigations, nor deep manipulations, after careful determination of conditions in the affected area.

7. While constitutional derangements demand attention and regulation, the local anomaly should receive adequate care. Sometimes powerful revulsives are needed, by blister, cautery, freezing, iodine, etc., always followed by strapping with zinc oxide plaster. The main cure, however, is always by manual treatment directed to the neuromuscular mechanisms followed by faithful and varied exercises *especially those which cause pain on movement.*

8. After due attention has been afforded by suitable measures applied to the constitution, to special organs, and to the affected area, there remains a need for functional education, in the form of (*a*) mental readjustment to the complex problems of chronicity, protracted disability, and previous disappointments, loss of confidence in performing movements, etc., and (*b*) reeducating the bewildered muscles to do their appointed work with precision and confidence.

9. Finally, the individual who suffers at any time from fibromyositis needs to learn and to practise thorough hygienic habits essential for his or her "diathesis" or "type of tissue cells" or "dyscrasia" or peculiarities of neuromuscular adjustments, or capabilities of elimination.

Among the first of these good habits (euthenics) is to live as much as possible out of doors, in all weathers, maintaining reasonable activities and, while not over-fatiguing, yet to beware of the one unpardonable sin of physical and mental stagnation, deterioration from disuse. Every day such sufferers should exert themselves so that they sweat fairly or freely.

THE TREATMENT OF INFECTIONS OF THE UTERUS AND CERVIX.*

PRELIMINARY REPORT OF 75 CASES.

By FRANCIS WARD LANGSTROTH, M.D.,

NEW YORK,

FORMERLY INSTRUCTOR IN GYNECOLOGY, NEW YORK POLYCLINIC HOSPITAL.

Fifty per cent. of all parous and twenty-five per cent. of all nulliparous women have infections of the genital tract. These infections are almost invariably located in the cervical endometrium. The cervical mucosa is of an entirely different type from that found in any other part of the female genital tract, and from the nature of its structure and the arrangement of its glands it is well suited to become a focus of chronic, bacterial growth. Sturmdorf has called it the tonsil of the uterus. The endometrium of the body of the uterus is practically immune to infection. Curtis[1] reports the examination of about 117 uteri; in only a very small percentage of these did the endometrium of the fundus show bacterial growth on culture, and the histological examinations failed to disclose the presence of inflammatory tissue. His findings agree with the work of Hitchman and Adler,[2] and Kundrat.[3]

Tears of the cervix can be entirely disregarded

*Read before the Mercer County, N. J., Medical Society, at Hightstown, June 3, 1919.

as a cause of uterine or pelvic symptoms. It is the presence of infection and not the tear that causes the disease. I wish to state boldly, as a result of my clinical and operative work, that in the future we will come to recognize that infections of the cervix are the fundamental cause of almost all the diseased conditions of the female reproductive organs, as well as the underlying factor in many of the conditions of general ill-health in the female.

There is no such disease as endometritis of the uterine body except when resulting from traumatism due to the introduction of foreign substances into the uterine cavity, and there is no excuse for the use of the uterine curette except for diagnostic purposes or for the removal of pedunculated fibroids or polipi. All the symptoms formally ascribed to corporeal endometritis are the direct result of infection of the cervical mucosa.

The bacteria that may cause chronic endocervitis are numerous. Among the more frequent are the gonococcus, the streptococcus, the staphlococcus, and the colon bacillus.

While the percentage of infection of the cervix in nulliparous women is high, it is not at all confined to those who have had sexual intercourse. These infections are not by any means always due to the gonococcus, but any of the above mentioned bacteria may be the causative factor.

Some of the results, symptoms and diseases, that follow from these all too frequent focal infections of the cervix are: (1) Transmission of infections both of the gonococcus and of other bacteria to the male. (2) Mental distress and physical discomfort in women so infected, on account of the leucorrhea which results from endocervitis. This leucorrhea is often most profuse and of a very offensive odor. This is of course a great trial to these women and a condition of which they are often too ashamed to consult even their family physician. (3) Disease of the uterus and pelvic organs. (4) Menstrual disturbances. (5) Tubal pregnancy. (6) Sterility. (7) Appendicitis and sigmoiditis. (8) Cancer of the cervix. (9) Constitutional symptoms and disease.

Let us next consider how chronic bacterial invasion of the cervical mucosa can act as a cause of the more serious sequences attributed to it above. And when I have done this, I bring before you a new gynecology, a gynecology based upon the incident of infection, and freed from all the myths and dogmas of the past. And should this not be so? Do the throat men any longer remove tonsils, or leave them alone, judging solely from their size? Is it not with them a question of infection? Do not the gastroenterologists consider that most of the diseases of the appendix, gall-bladder, etc., are the results of infection? The psychiatrists of today trace many forms of insanity to various focal infections.[7]

Gynecology was one of the first fields entered by the surgeon. We are told that ovariotomy was performed upon the Vestal Virgins by the surgeon-priests of Pompeii, and duplicates of their instruments can be seen in the Smithsonian Institute in Washington. Yet gynecology is the last special branch of surgery to shake itself free from the shackles of tradition, and to recognize the causes of these conditions as they truly exist.

Some day we may learn how inherited tendencies, or alterations in the secretions of the endocrine glands act to make one person susceptible, and another resistant, to infection, but until that time arrives we must credit to bacteria the rôle of causative factor in the production of disease.

In explaining how infective endocervitis causes the various pathological conditions mentioned above, the anatomy, histology, and physiological functions of the female generative organs must be studied minutely, but this would prolong this paper far beyond the limits of the reader's patience. However, I will endeavor briefly to indicate some of the pathology of endocervitis. The lymphatics of the uterus, for all that they are generally so little mentioned, have been carefully studied out.[8] They start in the cervix as minute open spaces in close contact with the racemose glands of the mucosa. These spaces converge, forming thin-walled lymph channels which ascend between the muscle fibers composing the myometrium. These in turn anastomose to form the lymphatic vessels which lie just under the peritoneal covering of the broad ligament, draining outward—those from the cervix and lower part of the uterus into the pelvic glands, and those from the body of the uterus into the lumbar glands. It is through these lymph channels that the infective bacteria and their products spread, and not up through the cavity of the uterus and out through the tubes into the peritoneal cavity, before reaching the ovary. This dissemination of infections by way of the lymphatics is what we find in other parts of the body; then why should it be overlooked or denied in the uterus and its appendages? Of course hemotogenous transmission of infections must not be ignored. Have not Draper,[4] Stewart and Barber,[5] as well as others, shown conclusively that ascending infections from the bladder through the ureter to the kidney are practically impossible except in the presence of severe damage to the ureter and its sphincter?

Thus we have from an infective endocervitis an ascending intramyometrial lymphangitis, with its accompanying round cell infiltration, serous exudation and plasma cell formation, with its resulting fibrous tissue proliferation, and the implantation of the infectious organism upon new areas, frequently the tube, and less frequently the ovaries. These processes continuing for perhaps years cause chronic destructive changes in the uterus, broad liguments, tubes, and ovaries.

We now know that the uterine muscle possesses inherent rhythmical contractions,[9] and that these contractions occur just as regularly, but with less frequency, in the non-gravid as in the gravid uterus, and it is largely by means of these contractions that the venous circulation in the uterus is accelerated, as the veins of the uterus have no valves. These contractions also tend to promote uterine drainage. In the uterus that has been for a long time subject to this chronic lymphangitis with its accompanying formation of fibrous tissue, these contractions, which are increased during menstruation, naturally become painful, just as the movement of any inflamed muscle bundle is painful. Thus do we explain those symptoms generally spoken of as dysmenorrhea. This same chronic inflammatory process, spreading upward by means of the lym-

phatics, in time causes a thickening of the ovarian tunic, which thickening delays the rupture of the Graafian follicle, so that the period is delayed, causing amenorrhea. Or, perhaps two follicles will rupture within a short time of each other, thus forming a double period, or one form of metrorrhagia. At other times, the Graafian follicle, having ruptured, remains, on account of the thickening of the tunic, unabsorbed, thus causing the prolongation of the period, or another form of metrorrhagia or metrostaxis. In the more virulent infections of the cervix the disease spreads more rapidly, causing acute or chronic pyosalpingitis. In those infections of a less virulent or chronic nature the serous and muscular coats of the tubes become gradually thickened, the tunic of the ovary, as has been mentioned, also becomes thickened, resulting in unruptured follicular cysts, while the plastic exudate forms bands of adhesions which kink the tubes and eventually drag them and the ovaries into the cul-de-sac. In some cases the tubes become partially or totally occluded, thus causing sterility, even if the spermatozoa escape the destructive action of the pus cells in the cervical canal. I believe that this thickening, kinking, and loss of peristaltic motion of the tube are frequently the cause of tubal pregnancy. I was able to demonstrate this very plainly at one of my operations. These infectious processes may further spread to the appendix and sigmoid.

I have stated that chronic, cervical infections can be the cause of serious, general ill-health. I want to give a very brief history of one case operated upon.

This case is No. 56 in the series. Patient is twenty-nine years old, married. Was perfectly well and healthy until her first baby was born three years ago. High forceps delivery; the baby died. The patient became infected, "flowed" for about a month; the following summer she spent three weeks in hospital, taking a sort of rest cure for nervous prostration. She later ran a temperature of 104° and was sent to the hospital and treated for infected kidney. She has had headaches ever since the first child was born, and always felt tired and lost weight; also has had a great deal of backache. She became pregnant again in August, 1917; the baby is now seven months old. Felt very well while carrying child. No instruments were used in the delivery. Wore a pessary for about three months after second delivery for displacement of the uterus, but it did not do any good. Had headaches regularly every two weeks. No stomach trouble; no bilious attacks. Had jaundice when about eight years old; tonsils have been removed. No other illness.

Physical examination showed the perineum badly lacerated; cervix also badly lacerated and infected; moderate enlargement of the left tube and ovary; uterus retrodisplaced down in the hollow of the secrum; is hard to replace. No cystocele; triangular ligament is intact. There is a very profuse discharge. The patient has a very small umbilical hernia.

Operation: Upon inspection the cervix is seen to be lacerated bilaterally; the mucosa covering its vaginal surface is bright red in color, with several bluish, almost gangrenous areas where Nabothian cysts are evidently pointing to its vaginal surface. The condition of the vaginal mucosa of the cervix is such that it seems doubtful if a proper flap can be obtained. There is a profuse discharge from the cervix. The enucleation was successfully carried out. At the request of the attending physician the perineum was not repaired. The recovery was uneventful. A culture was taken and proved to be a *Staphlococcus hæmolyticus*. A vaccine was ordered made from this culture and numerous doses were given by the attending physician; a slight reaction followed even small doses. The gynecological recovery was rapid and satisfactory; all leucorrhea disappeared. The latest report, received within a few days of the time of writing, states that this patient has made a complete recovery as to her general health. Her headache and backache have left her, and she feels strong and in good health.

This case is of especial interest for several reasons: (1) Her ill-health dated entirely from her first labor. (2) Her symptoms pointed to some general, rather than to a gynecological, condition; in fact, one specialist considered that she had symptoms of hyperthyroidism; and she had previously been carefully examined for all focal infections excepting of the cervix. The gynecologist to whom she had been referred took into account only her retroversion, which condition, as the ultimate results in this case show, was not the cause of her symptoms. (3) Nothing whatever was done for this patient excepting the "plastic conical enucleation of the cervix"; and no medicine whatever was given, excepting the autogenous vaccine mentioned. (4) Her recovery seems to be complete.

I have outlined briefly the method by which I believe chronic infections of the cervical mucosa cause the more important symptoms and diseases that I attributed to it in the early part of my paper, excepting, perhaps, the most important one of all, namely, cancer of the cervix. However, to consider the subject of cancer of the cervix now will prolong this paper unduly, and I will leave its consideration to another time.

I suppose this article might not be considered complete without some brief reference to the diagnosis of cervical endometritis; although the diagnosis is so simple that little time need be devoted to its consideration. Leucorrhea is present in all cases, varying from the profuse discharge of creamy pus seen in acute Neisserian infections to the yellowish or greenish tenacious secretion of the chronic endocervitis due to infections by other organisms. In the gonorrheal infections, the mucosa at the mouths of Skene's glands will be found reddened, swollen, and everted, and for years two minute red points will remain visible at the orifice of these glands, as a constant sign of a gonorrheal infection. Upon digital examination the cervix will feel harder than normal, and will be found to be studded with nodules varying in size from a pin point to a pea. These are formed by the infection occluding the ducts of the racemose glands, causing retention cysts. These are usually called Nabothian follicles, and I believe are always pathological. There is generally to be noted a periadnexitis, which seems to be more frequent on the left side. If the cervix is inspected there will be seen a discharge varying in character with the kind of infection and the length of time it has existed. The lips or edges of the external os are red, sometimes almost purple, more or less swollen and everted. There is a proliferation of the cuboidal epithelium of the canal, which overrides the squamous epithelium of the vaginal surface; this gives the appearance generally spoken of as an erosion of the cervix. In some infections the vaginal mucosa of the cervix and the adjacent part of the vagina will present a petechial rash, which closely resembles the so-called raspberry or strawberry tongue seen in scarlet fever and some other acute infectious diseases. I believe this occurs when the infection is due to some form of streptococcus. Again there will be areas that will appear

almost gangrenous; or the infected cysts can be seen pointing as minute abscesses upon the vaginal surface of the cervix.

What has been done for these cases in the past? Applications of iodine in the form of Churchill's or the ordinary tincture, silver nitrate, in almost all known strengths, copper sulphate, etc., followed by tampons of gauze, cotton, and wool, medicated with ichthyol, glycerin, boroglyceride, iodine and glycerin, etc., to say nothing of the various forms of electrical treatments, violet ray, radium emanation, etc. To be brief the usual round of gynecological treatments, all the benefits of which accrue to the physician rather than to the patient. When these treatments failed, as fail they must, the surgeon was called upon to ply the curette after first carefully dilating the cervical canal. At times this last procedure was followed by a more or less temporary benefit, due largely to the improved drainage (which drainage, however, was not permanent), rest in bed, a change of surroundings, and freedom from household cares. Frequently the use of the curette only carried the infection into the uterine cavity and inoculated a previously sterile corporeal endometrium, leaving these cases worse than they were before, many of them even having died from a resulting septicemia; and this would have happened more often no doubt, if these patients had not already developed an immunity to their special infection.

In the course of six months or a year, these cases generally returned to the surgeon complaining of pelvic symptoms and were operated upon for some tuboovarian conditions, and likely curetted again. In many of these cases, the other tube and ovary would have to be removed in a year or two, or more likely a hysterectomy would be necessary.

Many times, even when a supravaginal hysterectomy was done, the unfortunate patients were not cured, since the infection that still existed in the cervical stump would cause an inflammatory condition at the base of the bladder, sometimes involving the lower portion of one or both ureters, and so keep up the pelvic pain and irritation.

This picture is not exaggerated, but is based upon actual cases that have come under my observation.

What then, can be done for these women, who are so unfortunate as to have developed cervical infection? Properly directed surgical interference offers, at present, the only method of *cure* for these cases. The infected cervical mucosa must be entirely removed, for any portion remaining only acts as further foci of infection.

After completely enucleating the cervical mucosa, being careful not to cut away any of the muscle, so as to preserve the function of the cervical canal intact in case of future pregnancies, the cervical canal must be relined with a flap of mucosa dissected from the vaginal portion of the cervix. I have named this operation "Plastic Conical Enucleation of the Cervix." So far as I know, this is the first clinical report covering a series of cases operated upon by this method. To Dr. Arnold Sturmdorf[6] belongs the credit of first describing the operation and of working out the pathology of cervical infections, and I wish to express my appreciation of his highly valued help and suggestions, during the time that I had the pleasure of being associated with him at the Polyclinic Hospital. I now have under observation seventy-five cases that I have operated upon by this method. Some of these cases date back over three years. These cases I will report in detail in a later paper, but I will state here that practically every woman operated upon by this method, in which the pelvic condition had not progressed too far, was cured of her leucorrhea, menstrual disturbances, backache, etc. All of the cases were improved in general health, and I have a report from the State Hospital in Trenton, N. J., where I have performed a number of these operations, of nine cases cleared up mentally almost immediately after "plastic conical enucleation" was performed, although previously every other known source of infection had been removed.

CONDITIONS WHICH AFFECT THE OCCURRENCE OF RECTAL DISEASES IN INFANCY AND CHILDHOOD.

By ARTHUR A. LANDSMAN, M.D.,

NEW YORK.

ASSOCIATE RECTAL SURGEON POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING RECTAL SURGEON PHILANTHROPIN HOSPITAL; DEPUTY SURGEON DISEASES OF THE RECTUM, OUT-PATIENT DEPARTMENT NEW YORK HOSPITAL; PROCTOLOGIST HEBREW ORPHAN ASYLUM.

It is well known that diseased states are favored by special conditions, which either bring about their development, or prevent their occurrence. These are to be looked for in the agent which causes the disease, and the person affected by it; his physical, psychic, and social conditions, and the manner in which he reacts to his surroundings. Such factors as age, heredity, sex, habits, and environment have long been recognized as bearing definite relationship to the incidence of all disease, and hence they require our careful scrutiny. Of these none is more important than age, which, while possessing immunities of its own, also carries liabilities to many disorders from which maturity is free; the proctologist has frequent occasion to observe that though certain rectal diseases are comparatively unknown among children, there are others which prevail with relative frequency at this period of life.

It would be folly to assume that this is the result of accident or chance; the more we study the subject the clearer does it become that it is the logical outcome of conditions which are to be found in the anatomical state of the parts, their functional activity, and the habits and environment of the individual. In order to see whether it is possible to

find in these a rational explanation of the occurrence of rectal disease in children, we must examine on this basis the differences between the conditions existing in the child and the adult, and try to learn in what manner childhood would predispose to such deviations from the normal as are seen in certain rectal affections at this period of life.

To begin with, we must not lose sight of the fact that the rectum is in intimate contact with the bones which form the posterior wall of the pelvis, being closely adherent to them by means of the intervention of the endopelvic fascia, and following the curves on their anterior surfaces to the termination of the bones; hence any difference in their shapes must be marked by a corresponding difference in the curves of the rectum, and in the degree of mobility of the organ. An examination of the infantile sacrum shows it to be relatively flat, shallow, and less curved than that of the adult, while the coccyx is soft, yielding, and its joints more freely movable because there is no ossification between its segments until middle life; in agreement with this the rectum would acquire a tendency to become more straight in its course and direction, and to that extent to lose the essential support to which the shape of the bones contribute to such a marked degree. In accordance with principles of mechanics, force applied on an object through a vertical axis produces a greater effect than when exerted through one which is curved, as illustrated in the construction of the spinal cord whose strength is in no small measure due to its arrangement in curves. This offers a reasonable explanation of the frequency of prolapse of the bowel in children, in whom such exciting causes as diarrhea, whooping cough, and malnutrition from artificial feeding excite straining at stool, produce increased abdominal pressure, and bring about further loss of support from absorption of connective tissue—factors which need not be seriously considered in the adult. We see approximately five cases of prolapse in children to one in adults.

Procidentia recti is by no means the only rectal disease to which the structural conditions existing in the child predispose it, but as it presents a striking illustration of their effect, it has been selected as a good example in this discussion; but we cannot leave the subject before considering some of the congenital defects in children, which are responsible for disease of the terminal bowel.

These are mostly dependent upon the failure of the two parts which form the embryological rectum, the caudal extremity of the hind gut, derived from the endoderm, and the proctodeum, derived from the invaginated ectoderm, to unite properly. Other defects are due to failure of fusion or absorption connected with the cloaca, the primitive reservoir through which, in its final modifications, the urinary and intestinal excretions are expelled from the body. Here again we must limit ourselves to only the commoner examples. If something occurs which prevents the proper joining of the enteron and proctodeum as they grow towards each other, there remains a varying degree of developmental defect, which may run the gamut from a thin band which bisects the canal, to partial congenital stricture, and even complete atresia ani.

A case in point, is that of a child of 3½ months, on which I recently operated on the service of the Philanthropin Hospital, which presented an anteroposterior band continuous with the median raphé, obstructing the anal opening; when this was ligated and cut, the canal was found to be closed, with the exception of a minute opening at its center, for a distance of 2 cm., through which the soft feces were discharged on each side of the band. As the child grew older and the stools less soft, symptoms of chronic intestinal obstruction appeared, which disclosed the condition, and led to the operation.

Defects which originate in the cloaca, result in abnormal connection of the rectum with the urinary and genital apparatus, so-called congenital fistulæ, which, when extensive, are a menace to health, but in their minor grades sometimes persist unrecognized throughout life.

While these defects are rather uncommon, they are exceedingly important from the prognostic standpoint, and should be looked for by the obstetric attendant immediately after delivery, not by mere inspection of the anus, but by insertion of the little finger, and observation of the urinary function. In an experience of several years in a busy rectal clinic, as well as in private practice, only two cases of congenital anorectal defect were seen in over 8,000 patients; other authors report one in about 5,000 births.[2]

When next we turn our attention to the problem of the functional activity of the organs as they affect rectal disease in the infant and young child, we learn that here too there are conditions which produce varying results at different age periods. Defecation, so far as it applies to infancy and young childhood, is an involuntary act, the resultant of automatic function which proceeds in a normal and orderly manner as long as there is no interruption in the reflex arc which carries the impulses. While there is but a small quantity of stool within the intestine, insufficient to start a stimulus, the organism feels no concern to expel it, unless a desire is initiated voluntarily, or is forced upon it by the toxic character of the contents; but no sooner does the intestine distend to a certain degree than the mass becomes to all intents and purposes a foreign body, and a stimulus is at once started to the center in the lumbar cord, from which, without the intervention of the conscious mind, impulses are transmitted to the circular and longitudinal muscles of the gut, and to the structures in the pelvic floor concerned in the act of defecation. Such is not the case in the adult, however, in whom, as the requirements of civilization, the expulsion of the intestinal contents is generally postponed to a convenient time, and the process is performed as an act of volition. In other words, there is automatic regulation while wisdom and discretion are still undeveloped, succeeded by an adjustment under the control of the will, when they are ready to be exercised to the advantage of the individual. It is evident that a natural function, such as has been here described, carried on by means of a device shown to exist in the infant, will result in a prompt, regular, and complete evacuation of the intestinal contents; there will be no tendency for the accumulation of material from which absorption of noxious products may take place, which will irritate the nervous mechanism, obtund its sensibility, and

injure the muscular tone. These are the conditions in infancy and early childhood, as opposed to adult life, but there are still others which exert a favorable influence: children enjoy better digestion, live on a more suitable diet, and produce richer intestinal secretions; their reflexes are more acute, their vital processes more active, and their stools softer and expelled with less strain. They are not exposed to the ill effects of alcohol and tobacco, or to vicious habits which cause congestion of the pelvic organs; menstruation, pregnancy, and labor are absent from the normal cycle of their lives, and they are free from many other fruitful sources of disease of the rectum. Is it a wonder, then, that hemorrhoids, one of the commonest diseases which affect the adult of the human race, are rare among children, and practically non-existent among nursing infants? In an experience covering several years, the youngest patient whom we saw suffering from piles, was a bottle-fed child of 2 years, though others report cases earlier in life.[3] To be sure, a diagnosis of piles made by the mother, and sometimes by the physician, often enough turns out to be prolapse, or solitary polyp; and if we may be allowed to digress a moment, the latter is equally common in adults and children, but it is interesting that multiple polyposis is seen practically only in adults. The significance of this statement becomes apparent when we recollect, that 80 to 90 per cent. of these sooner or later terminate in death from malignancy.

"Man is a creature of heredity and environment," has been repeated again and again with a truth which becomes more evident to every generation of medical men. The former plays a numerically small, but inherently important role in the occurrence of rectal diseases among children, especially in the early manifestations of syphilis which are occasionally seen in rectal clinics, such as ulcerations, condylomata, and the cracked and fissured condition of the anal ring which is the outward symptom of luetic proctitis; environment contributes its full quota to the development of rectal disorders, notably such as are promoted by overcrowding and other unhygienic conditions, intestinal disturbances from unsuitable food, and the dirt and filth which seems to be inseparable from poverty in its worst forms. In this class we might include diseases due to parasites, such as thread, pin, and tape worm; these cases are usually referred for the treatment of the anal pruritus, often the most annoying symptom.

Finally, in conclusion, we should like to mention two conditions which have only negative significance in this discussion, the so-called dermoid cyst, which is very rare in childhood, and malignant tumors, of which a few examples are cited in literature.[4]

Summary.—Rectal diseases occur with varying frequency in childhood and adult life, some being more common in children, others in adults; their presence or absence is not due to chance, but depends upon well-defined variations in the anatomy of the parts, the functional activity of the organs, and the environment of the individual.

Medical and Surgical Lessons of the War.

IRRITABLE HEART IN SOLDIERS AND RECRUITS.

By JONATHAN MEAKINS, M.D.,

MONTREAL, CANADA.

ATTENDING PHYSICIAN, ROYAL VICTORIA HOSPITAL; RECENTLY COLONEL, C. A. M. C.

During the last five years when many countries have had to take careful stock of their man-power, any physical condition which made conspicuous inroads on its efficiency had to be thoroughly investigated. Naturally these conditions were diverse but could be roughly divided into those which were of known cause, such as battle injuries and certain infectious diseases, and those in which the mechanism was still obscure. In the latter class must be included "Irritable Heart of Soldiers." That this is a condition especially confined to the military class there is now no reason to believe. When a country is at war and mobilizes its man-power, either by conscription or by voluntary enlistment, the general health and vigor of the country is of prime importance. A large proportion of the male population of the civilized countries of to-day lead a more or less sedentary life. Not that this necessarily predisposes the population to certain diseases, but it militates against determining by past experience what physical endurance any individual may be capable of performing under given circumstances. It is in relation to this important fact that the condition known as "Irritable Heart of Soldiers" assumes great importance. This symptom-complex is not one wholly confined to soldiers, but it is only of conspicuous importance when a large body of men have to do a given amount of physical exertion more or less uniformly. They are all under the same approximate physical and nervous strain, as it must be presumed that only men employed as first-line troops are to be considered soldiers. Those who do the less arduous tasks, many of grave importance to the army, are not called upon to endure as an individual part of a concrete fighting unit, the gruelling duties of forced marches, exhausting advances through heavy country, or prolonged resistance to an elated and temporarily victorious enemy.

Thus there are two main divisions of the physically unfit. The recruit who by trial cannot be made into a first-line soldier, and the soldier who through some accident of warfare has been rendered temporarily or permanently unfit for first-line duty. In so far as part of these cases are concerned where there is an apparent and obvious disability due to either previous disease or to a battle casualty, this paper is not concerned. These conditions will be dealt with elsewhere. But there is one broad class of cases which for army purposes has been called "Irritable Heart of Soldiers," which must be considered both from the standpoint of the recruit as well as from that of the invalided soldier. The principal symptoms of this condition or symptom-complex are dyspnea, palpitation, dizziness, exhaustion, and precordial pain, one or all of which may be present, and be greatly aggravated *by exertion*.

It must be conceded that, apart from any concrete physical disability, these symptoms form a group which would of necessity play a great rôle in rendering a man unfit for prolonged or sudden physical endurance. In dealing with this question it may be well, in order to clear the ground, to begin with the recruit.

Recruits.—In recruiting for an army during a time of war, the methods must depend upon the urgency of the occasion. In the majority of countries war means urgency of the highest degree. Under these circumstances whether the army be raised my conscription or by volunteers the number to be enlisted will be in proportion to the manpower resources of the country. Therefore it is impossible to sort out all the recruits in the most scientific and exact manner; except that all obvious disabilities are of necessity eliminated. But the final selection must take place when the men are in their depots under intensive training, and then the spirit of patriotism is ofttimes so great that the weaker members will go frequently to all lengths to disguise their physical inefficiency. On the other hand, if an army be raised under ideal conditions when each recruit may be thoroughly and systematically examined, a higher degree of eventual physical efficiency should be obtained. Comparative leisure and many expert examiners are necessary under these ideal conditions. Then a large number of men who give symptoms of "Irritable Heart" as an indication of some well-recognized disease may be eliminated. These diseases are chiefly tuberculosis and hyperthyroidism.[1]

After eliminating these cases from the class of recruits, there are left a certain number which for no obvious reason suffer from the symptoms of "Irritable Heart." In order to avoid repetition, these will be classed with the cases which are recognized in soldiers on active service, as many of the main principles are applicable to all.

A great deal of effort has been spent during the past four years in elucidating this problem: as yet no definite pathology has been discovered to account for this symptom complex. Until this has been placed on a firm and concrete basis all effort has been expended in attempting to account for the various symptoms, and, if possible, to correlate them into an intelligible whole. The most exhaustive work published on this subject was that undertaken by Lewis and his associates.[2] In so far as the symptoms were concerned, they undertook an analysis of them in all their diverse manifestations. Necessarily the history and etiology of this condition was likewise subject to minute scrutiny in order if possible to arrive at a common basis of cause.

Their analysis of the symptoms cover the subject very thoroughly. The preceding history of their cases throws strong light on possible etiological factors. The experience of others does not change the broad interpretation of the characteristics of the symptoms but there has been a certain divergence of opinion as to whether one etiological factor or another plays the predominating rôle.

In regard to treatment, little or nothing of a specific nature may be accomplished until the common etiological factor has been definitely determined or this large class of cases broken up into separate groups based upon definite pathological entities. In the meantime much has been done to determine the extent of the disability; to rescue those of the milder type and to prevent others from becoming chronically affected.

In order that a proper conception of this condition may be obtained, it would be better to consider the symptoms first, and later to deal with the probable causes and treatment.

SYMPTOMS.—(1) *Cardiovascular.*—As the name would imply, symptoms referable to the cardiovascular system play an important rôle in this condition. The patient not only complains of them very frequently, but they originally impressed themselves most prominently upon the physician.

(*a*) *Pulse-rate:* At rest the pulse-rate may be approximately normal but as a rule it averages about 90 per minute. There is great difference between individual cases. There may be a conspicuous bradycardia of 50 to 60 per minute. This, however, is very exceptional. On the contrary it is not unusual to meet cases with a pulse-rate between 110 to 130 per minute even after prolonged rest in the recumbent position.

On exercise the pulse almost uniformly increases in rate. This increase, as a rule, is in proportion to the amount of exercise accomplished. The greater the exercise, the greater the increase, which is quite in accord to what usually occurs in the normal individual. But in cases of "Irritable Heart" the increase is much greater and more disturbing to the patient. He has an acute feeling of distress and palpitation, which renders further exertion almost impossible.

The relationship between the normal and abnormal is one of degree. Under a given amount of exertion the normal pulse-rate may increase to 120 per minute, while in a case of "Irritable Heart" it may increase to 140 or even to 180 per minute on the same amount of exertion. But, on the other hand, if sufficient exercise be given to a healthy individual and to a patient in order that both may experience the same general symptoms, it is found that the pulse-rate at the end of the exercise will be approximately the same, although the patient may have done much less work than the normal.[3]

A very important point in regard to the pulse-rate is the time which elapses before the approximate normal is resumed after exercise. It will be found upon experiment that in comparatively healthy individuals the pulse-rate resumes the approximate normal within a fairly definite period of time after exercise is completed, depending upon the amount of work accomplished. In the severer cases of "Irritable Heart" there is a tendency for the pulse-rate to show a definite delay in the return to normal after exercise. In such cases there is a conspicuous inability to accomplish more than very moderate physical work.[4] [29] .

The effect of sensory stimulations on the pulse-rate is also conspicuous in these cases.[29] This is particularly of importance when it is appreciated that many of these cases may be in a highly emotional condition. It has been determined that there is a close relationship between the response of the pulse to emotional stimuli and the capacity of the patient to accomplish physical work. In those least capable of exertion there is the greatest abnormal

response of the pulse-rate to emotional stimulation.[4]

It might be considered probable that rest in bed would affect beneficially this tendency to tachycardia on physical and nervous stimulation. Meakins and Gunson[5] tested this in a practical manner. They made careful determinations of the pulse rate in a series of cases under varying conditions of exercise over a period of some days. They then placed these patients in bed absolutely at rest for a week, and then made similar observations on the pulse rate after exercise. It was found that there was a conspicuous increase in the symptoms, as well as a higher pulse rate immediately after exercise, and a greater time elapsed before the pulse rate returned to normal.

(*b*) *Size of the Heart.*—It has been considered by some observers that the heart, in this condition, is definitely enlarged. It is important to establish this point one way or the other. In order to do this an exact means of measurement would be necessary. This has been accomplished by means of the orthodiagraph. Meakins and Gunson[6] have shown that in comparison with normal individuals of the same weight there is a distinct diminution in the cardiac diameter when at rest. Further, they have shown that whereas the normal heart becomes distinctly smaller on exercise, it does not show this change in cases suffering from conspicuous symptoms of "Irritable Heart."

(*c*) *Blood Pressures.*—It has been determined that there is little or no difference at rest between the systolic blood pressure in cases of "Irritable Heart" and the normal.[3] If, however, the patient be up and about, a certain increase of the systolic pressure is found. This most probably is due to the effect of emotion or of exercise. On exercise undertaken at a given rate and of a given degree, there is a distinct increase of the systolic pressure in the patient over that found in the control under similar circumstances. Furthermore, the blood pressure remains elevated for a longer time than is the case in the control.

(*d*) *Precordial Pain.*—The complaint of pain over the left breast is a very common one. This is usually increased by exertion and emotion. There is also found frequently a direct connection between the onset of the symptoms and this complaint, in that the pain may at this time be very acute and leave a lasting impression on the patient's mind. It has been found in cases suffering from considerable precordial pain that a definite area of hyperalgesia may remain for a considerable period of time. The distribution of this hyperalgesia may vary from a single rib space to an area extending over the whole left anterior chest up the left side of the neck to the mastoid, and even down the inside of the left arm to the hand. In certain cases the distribution of the pain and the hyperalgesia bears a close relationship to the pain experienced in angina pectoris;[7] a further similarity may be noted in that exertion increases the hyperalgesia and pain in both these conditions. A further point of great interest is the conspicuous exacerbation of the pain and hyperalgesia during the course of an intercurrent infection.

(*e*) *Apex Beat.*—The extent and force of the apex beat has been considered as an indication of dilatation of the heart. But by orthodiagraphic measurement this was found not to be the case in patients suffering from "Irritable Heart." In fact, it was determined that those cases showing a diffuse or forcible apex beat had, on the average, a cardiac area smaller than normal, and no larger than other cases of "Irritable Heart" which had a normal apex beat.[6]

(*f*) *Cardiac Murmurs.*—Lewis[3] has made an exhaustive study of the importance of murmurs in the prognosis of these cardiac disabilities. His observations have been based on a rare and extensive experience in the examination of such patients, and he has had exceptional opportunities of determining the eventual capacity of such soldiers to accomplish work. After excluding all cases of well-marked organic disease of the heart he comes to the following conclusion: "The presence or absence of systolic murmurs is of no value in estimating the soldier's capacity for work; this practical conclusion holds irrespective of the character, conduction, or point of maximal audibility of the murmur in question."

Kylin[9, 10] examined 507 men for the presence of cardiac murmurs, and found them present in 97, or 19 per cent., exclusive of organic heart disease. By direct observation he was impressed by the fact that those with systolic murmurs were unable to stand physical effort as well as those without murmurs. Also that the men with murmurs were more nervous than the controls. Kylin concludes that a large number of men with accidentally detected murmurs have less physical resistance, and so are less fitted than those without murmurs to undergo the fatigue incidental to first class troops.[27]

Although these views seem to disagree, the fact remains that the presence or absence of an accidental systolic murmur is no direct criterion as to a man's power of physical exertion.

(2) *Respiration.*—Shortness of breath is one of the most common complaints of men suffering from "Irritable Heart." It is not only one of the commonest, but it is also one of the most disabling. The cause of this symptom appears in some ways to be almost the cornerstone of this symptom complex, and as yet has not received as great attention as it deserves.

(*a*) *Rate of Respirations.*—At rest. The respiratory rate may be raised but little above the normal while at rest. On the other hand, in severe cases it may be constantly between 40 and 50 per minute. Even in the least affected cases the respiratory rate is on the upper limits of normality. During sleep the respiratory rate of normal individuals is between 8 and 14. In these patients it is seldom lower than 20 per minute. At times definite periodic breathing has been observed in the severest cases while asleep.

On exertion.—The respiratory rate is almost invariably increased beyond normal on the slightest exertion. Under circumstances which would not disturb the rate in a normal person there may be an acceleration to 60 or 70 per minute in these patients. It is almost uniformly this abnormal hyperpnoea on mild or moderate exertion which is so incapacitating to the individual as a soldier. The soldier being a part of a uniform whole, cannot take his own time, but must keep up with his stronger comrades, and it is usually the intense

distress consequent upon this "shortness of breath" which necessitates his falling by the wayside.

(*b*) *Depth of Respirations.*—At rest. The depth of the respirations of a normal individual when at rest varies between 400 to 600 c.c. per respiration. In these patients it is seldom that each respiration exceeds 400 c.c., and according to the severity of the symptoms so will the volume of each respiration diminish, until in the most severe cases the average volume of each respiration may not be more than 200 c.c. It is quite apparent that the smaller the volume per respiration, the greater, of necessity, will be the respiratory rate. As a consequence, it has been found that the total ventilation is also increased. Whereas the normal pulmonary ventilation per minute is 8 to 9 liters, in these patients it is usually between 10 and 15 liters. It is only in the severe cases that respiratory distress is appreciable when at rest.

On exertion.—In the normal person, the need on exertion for increased respiratory exchange is accomplished by increasing the depth of the individual respirations, and it is only when the work becomes excessive that the respiratory rate appreciably increases. In these patients the depth increases but slightly, while the increase in the ventilation is accomplished by increasing the rate.[13] This is a very wasteful method. It is found that in order to maintain an efficient respiratory exchange the patient may have to increase the total ventilation to 35 or 40 liters per minute, while on the same amount of work a normal person's total ventilation would amount to little more than 20 liters per minute.

The reason for this abnormal increase of the respiratory rate is to be found apparently in an increased sensitivity of the Hering-Breuer reflex, whereby it is released between abnormally narrow limits. This reflex through the vagus controls the point at which inspiration shall be inhibited and expiration initiated. Haldane and Mavrogardato[11] have shown that this reflex is in return regulated by chemical stimuli. In these patients, therefore, it seems quite clear that there is a derangement of the normal equilibrium between the Hering-Breuer reflex and the hydrogen-ion concentration of the blood. As a result the reflex acts prematurely, restricting the expansion and contraction of the lungs. The result of this restricted type of breathing has been shown experimentally to produce definite signs and symptoms of anoxemia,[12] such as periodic breathing, palpitation, headache, tingling of the extremities, and dulled mental faculties, as well as the compensatory changes of polycythemia and reduction of the bicarbonate reserve.

This anoxemia, which may be constantly present in the severe cases, is produced by exercise in the more moderate cases, and will most probably account for many of their symptoms.

Certain of the cases are troubled with disturbed sleep. They complain of vivid unpleasant dreams, paroxysms of coughing, and of shortness of breath. In some of the severe cases definite periodic breathing has been observed during sleep. In normal people the respiratory rate usually declines to between 8 and 14 per minute, while in cases of "Irritable Heart" it seldom goes below 20 per minute. Here again we have an abnormally high respiratory rate as compared with the normal. It has been demonstrated that when in the recumbent posture anoxemia is more easily induced by restricting the depth of breathing than in the upright position. It therefore seems probable that these cases may all suffer from more or less anoxemia during sleep.

The effect of anoxemia on the nervous system and general well-being or "condition" of an individual is well recognized. The symptoms produced by this condition are very analogous to those of "Irritable Heart," as, for example, "mountain sickness." The relationship between the anoxemia and the symptoms of these patients will become more apparent when the other systems have been discussed.

3. *Nervous System.*—These patients show a considerable degree of nervous instability. They are irritable, lack mental concentration, and exhibit considerable physical and mental depression. This is not, as a rule, as pronounced as is found in severe cases of neurasthenia, but yet is much removed from the normal. Besides these mental symptoms there are others of a more or less objective nature. A large proportion of these patients exhibit a tremor of the hands. This may be so conspicuous as to strongly suggest the presence of hyperthyroidism. It is of a fine character, and is exaggerated by exertion and any mental excitement.

Giddiness is also a common symptom. It may result from change of posture from the recumbent to the upright position, but more commonly occurs after exertion.

Lewis, Cotton, and Rapport[5] thoroughly investigated this subject. They found that certain cases exhibited a considerable drop (30 to 40 mm. Hg.) of blood pressure when the position was changed from the recumbent to the upright. This was accomplished without exertion on the patient's part by means of a swingboard. Such a gross change was so exceptional, and the results of change of posture so inconstant in a group of cases, that they came to the conclusion that "Beyond the statement that postural giddiness in these patients seems to be associated with faulty distribution of the circulating blood during the period of giddiness, it is impossible for the present to proceed."

The presence of giddiness after exertion is very common in these cases. There is no evidence that this is the result of any conspicuous fall in blood pressure immediately exertion ceases. The fall of blood pressures (systolic or diastolic) and the pulse rate after exercise are, as a rule, if anything, delayed beyond the normal. There are cases, however, where the sudden fall of systolic blood pressure might suggest the production of cerebral anemia. This is the exception. Giddiness is not always present in these cases, while it frequently occurs in patients in whom the pulse rate and blood pressures remain elevated longer after exercise than in controls.

The rôle played by anoxemia in the production of giddiness after exertion is important. This is a common cause of giddiness in comparatively normal persons. In these patients, if the exertion be pushed far enough, cyanosis may develop, and there occurs with this intense giddiness even associated with semi-consciousness. Administration of oxygen by means of a small mine rescue apparatus while at work prevents the occurrence of the cyanosis and

giddiness, but does not conspicuously reduce the respiratory rate.

There is associated sometimes with the giddiness on change of posture and after exertion a history of fainting. This symptom has been investigated by Lewis and Cotton.[14] They found that fainting may appear after unusual but trivial occurrences, such as venopuncture, or from standing at attention for a considerable period, or by a sudden stimulus, such as a rapid machine-gun fire or bombardment. In the cases they observed the most constant findings were a conspicuous slowing of the heart's action to 40 or 50 per minute, and a coincident fall of systolic blood pressure to below 60 mm. Hg. There were, however, occasional cases in which these phenomena did not appear. Although they attribute the main cause of the fainting attacks in these patients to increased vagal tone, they "are not convinced that this is the sole cause of loss of consciousness in these patients, and suggest that other forms of attack may still remain unexplored."

The psychoneurotic factor in cases of "Irritable Heart" has been investigated by Oppenheimer and Rothschild.[15] They have brought forward facts which go far to show that a large proportion of these cases have a positive family or personal history of a psychoneurotic factor. They have separated these cases into two distinct classes. In the first class are those who exhibit definite psychoneurotic factors in both the family and personal histories. In these a history of constitutional asthenia (pre-army debility) was found in 70 per cent., while in the second class, or those without definite psychoneurotic symptoms, a history of constitutional asthenia was found only in 12.8 per cent. The differences in the symptoms and length of service between these two groups are very conspicuous, and strongly point to the fact that this condition is not a clinical entity, but as investigation proceeds distinct and separate groups of these cases, with separate fundamental pathology, will in time be separated.

4. *Ductless Glands.*—On account of the frequent claim by certain observers that derangement of the function of the thyroid, or of the suprarenal glands, is the sole fundamental cause of these symptoms, they cannot be passed without notice. Such a conclusion must carry its own conclusive proof, and as yet this has not been forthcoming. On the other hand, Fraser and Wilson[20] carried out experiments with adrenalin injected intravenously. They found that some patients showed a more pronounced reaction, in so far as the subjective symptoms of pallor, flushing, vascular pulsation, and restlessness were concerned. These symptoms all passed off in the course of a very few minutes. The change in pulse rate and blood pressure was practically the same as in the controls; in fact, the typical adrenalin reaction to hyperthroidism was not observed. The intravenous injection of apocadeine in these patients produced a blotchy erythema, but none in the controls, while an increase in pulse rate greater than in controls was also observed. They came to the conclusion that the sympathetic nervous system in these patients is more susceptible both to stimulation and inhibition.

An enlargement of the thyroid in these patients is the exception; in fact, it is found no more frequently than in the ordinary run of normal people. Furthermore, the administration of thyroid extract gives no indication that these patients are suffering from hyperthyroidism. Hyperthyroidism may play a rôle in a certain small percentage of them, particularly in those with a long-standing history. But that this might account for more than a very limited number there is at present no evidence.

As yet, no observations have been recorded which would prove or disprove the rôle of deranged suprarenal function.

5. *Blood.*—The examination of the blood in these patients has revealed some interesting and important facts. Not only is this the case in so far as the cellular elements are concerned, but also in regard to the chemical reaction of the whole blood or plasma.

(*a*) *Red Blood Cells and Hemoglobin.*—Numerous reports have now been published concerning the changes in the percentage of the red blood corpuscles and the hemoglobin. Hunt and Price Jones[16] found a pronounced polycythemia in cases of "Irritable Heart," following gas poisoning. These cases, although showing all the symptoms of "Irritable Heart," in varying degrees, where especially conspicuous on account of the disturbances of respiration, and in particular nocturnal dyspnea. Levy,[17] on the other hand, in cases not the result of gas poisoning, found an increase in the erythrocytes but no increase in the hemoglobin. The occurrence of polycythemia in these cases appears to be a compensatory phenomenon to anoxemia, and is very probably only conspicuously present in those with pronounced respiratory disturbances.

(*b*) *Leucocytes.*—In all varieties of cases there is evidently an increase in the leucocyte count. This is most evident in cases which have recently undertaken any form of exercise. Grace Brisco[18] has found that at rest the average leucocyte count is 10,600, while the same type of patients, when up and about, shows 12,700, and immediately after exercise this rises to 15,000 or more. If, however, healthy men undertake exercise which produces the same degree of symptoms as is produced in the patients on a much milder exercise, the increase of the leucocytes will reach the same degree as it does in the patients.

The differential leucocyte counts by the same author have shown several interesting points. A high lymphocyte count is common, but the patients are subject to greater diurnal changes than is found in normal people. The chief change in the differential count occurs in the lymphocytes, which may vary in different cases from 25 to 75 per cent. of the total count, depending upon the amount of exercise taken.

Reaction of the Blood.—This has been investigated by several observers with various methods. Barcroft and his co-workers[18] found that there was a decrease of "buffer salts" in the blood, or, in other words, that the bicarbonate reserve was reduced. They have considered that this was the cause of the dyspnea. Apart from this investigation little work has been done on cases suffering from "Irritable Heart," except in those cases which follow gas poisoning.

Douglas[19] found a definite reduction in the alveolar CO_2 of patients suffering from these symptoms on

recovering from gas poisoning. These results might be open to question, perhaps, on account of the difficulty of obtaining satisfactory specimens of alveolar air from such patients, except that Haldane, Meakins and Priestley[12] found a similar reduction in the CO_2 in the alveolar air in the same class of cases, and that they also exhibited a pronounced reduction in the CO_2 combining power of the blood, or the bicarbonate reserve.[19] Drury[5] found that the CO_2 in the alveolar air of cases of "Irritable Heart" having comparatively mild respiratory symptoms was in the lower limits of normality.

There seems no doubt that there is a relative acidosis in these cases, but whether this is the cause or the result of the shortness of breath is a matter of difference of opinion.

The fact has been established, however, that by treating these patients either continuously[20] or intermittently[19] by oxygen the polycythemia and nocturnal dyspnea are removed, and the combining power of the blood for CO_2 returns to normal. On the other hand, cases of "Irritable Heart" not due to gas poisoning were not relieved of their symptoms to such a conspicuous degree,[21] and although estimations of the CO_2 combining power of the blood were not recorded in these cases, it is to be presumed that had this been reduced it would have returned to normal, as occurred in other cases where a similar reduction existed.

Haldane, Meakins, and Priestley[19] come to the conclusion: "That the CO_2 capacity of the blood is diminished, and that it varies very distinctly from day to day, the variation being abolished or diminished by oxygen. The results obtained point, we think, to a simple explanation of the acidosis which is said to accompany or even cause the symptoms of 'Irritable Heart.' These cases showed in a very definite degree the rapid, shallow breathing which is such a prominent feature in many such cases, and it follows from the results which we have previously published[12] that these patients must have been especially liable to suffer from anoxemia, particularly at night. It is most improbable, however, that the degree of anoxemia was constant. Now, it is well recognized that anoxemia lowers the CO_2 capacity of the blood; hence it appears probable that the cause of the low and variable CO_2 capacity of the blood of these patients was varying anoxemia; this was certainly due to the shallow breathing resulting from the disordered respiratory reflexes.

"We are driven to the conclusion, therefore, that the so-called 'acidosis' in cases exhibiting the symptoms of 'Irritable Heart' is a direct consequence of the varying degree of anoxemia which must occur in these patients as a result of their shallow type of breathing."

Etiology.—The study of the symptoms of this syndrome has not as yet given any definite indication of its pathology. In fact, the more it is investigated the greater appear the difficulties of correlating the diverse factors. When the causes are similarly studied a definite pathology becomes even more remote, and it seems more and more apparent that probably a number of closely allied conditions are being grouped together, which on further study may be separated into their proper spheres. For the purpose of simplicity the main etiological factors will be considered separately.

(*a*) *Infections.*—In the cases studied at the Hampstead Military Hospital by Lewis and his associates[2] the infectious diseases played a predominant etiological rôle. They found that 33 per cent. of the cases investigated dated their symptoms directly from convalescence of some infectious disease. Furthermore, they found that careful study of the histories gave evidence in 50 to 60 per cent. of the cases that the infectious diseases played a prominent part in promoting this condition in its initial stages.

Of the infectious diseases, rheumatic fever occupied a predominant place. In fact, in 12 per cent. of the cases the symptoms dated definitely and categorically from acute rheumatic fever. Other infections of importance were pneumonia, dysentery, trench fever, diphtheria, and pyogenic infections. The other 40 or 50 per cent. was made up of a variety of conditions, none of which were sufficiently prominent to make a definite or important division.

(*b*) *Gas Poisoning.*—Although in the cases studied by Lewis and his associates gas poisoning played a relatively unimportant rôle (3 per cent.), other observers have had experience to the contrary. Hunt and Price Jones studied a large number of gassed patients during the convalescent period,[18] and found symptoms of "Irritable Heart" in 56 per cent. of them. Other workers have published similar reports. Such contradictory statements must demand some explanation. If the matter is regarded in a broad manner this will be apparent. The cases dealt with by Lewis and his associates were a conglomerate series resulting from indefinite etiological causes. The cases which were gassed, however, were diagnosed as gassed cases, and remained as such during their period of convalescence, whether symptoms of "Irritable Heart" were present or not. It is common knowledge with those who have had experience in reserve depots in Great Britain that cases who have been invalided for gas poisoning remain classified as such, and that the main disability eventually resulting is "Irritable Heart." It must be pointed out, however, that the respiratory symptoms play an important rôle in these cases. Intrapulmonary signs are seldom found, while all the associated symptoms of "Irritable Heart" (palpitation, precordial pain, and exhaustion) are conspicuously present. The natural conclusion is that gassed cases are usually considered as such, and not as cases of "Irritable Heart." It must also be pointed out that certain gasses are more prone to produce these symptoms than are others. For instance, the suffocative gasses, such as chlorine, phosgene, chloropicrin, etc., are more frequently followed by these symptoms than are the irritative gases, such as mustard gas or Yperite. The fact is quite accepted that symptoms of "Irritable Heart" have been frequently observed in cases recovering from gas poisoning.

(*c*) *Shock.*—The experience of those who have worked with cases of shell shock, or the allied conditions which occur among soldiers on active service, is that symptoms of "Irritable Heart among these patients is comparatively common. This is likewise in opposition to the findings of Lewis and his associates. But what applies to the cases of gas poisoning likewise applies to these cases. When a soldier is invalided for shell shock he is treated, usually,

for this condition in a special hospital, where the psychoneurotic symptoms receive the most attention. But, nevertheless, the occurrence of shortness of breath and palpitation on exertion, paroxysmal dyspnea at night, and ready exhaustion, are also prominent and distressing symptoms.

In dealing with these last two etiological factors it must not be overlooked that concurrent infections may exert an important and perhaps essential factor in the etiology of the condition. In cases of suffocative gas poisoning a secondary pulmonary infection is very common. The observation has been made by Priestley that in cases of shell shock exhibiting symptoms of "Irritable Heart" a history of coincident infection is quite frequent. Up to the present this point has not been clearly defined, but it is essential to bear such a contingency in mind, and that as yet the exact sequence of events has not been definitely outlined.

(*d*) *Previous Habits.*—When analyzing the previous history of these patients several points must be taken into consideration. These include habits, occupations, and constitutional characteristics.

(1) *Alcohol.*—It has been found by Lewis and his associates[2] that alcoholism is comparatively rare among this class of patients. The principal reasons would appear to be either a conscientious abstinence, or experience that alcohol aggravates the symptoms. It will be shown that the majority of these cases are recruited from the sedentary occupations, and are, as a rule, of a weedy type. As a consequence, they are less apt to indulge in the excessive use of alcohol. It is quite conclusive that there is no evidence that alcohol plays a rôle in the etiology of this condition.

(2) *Tobacco.*—It has been claimed by some observers that the excessive use of tobacco is the cause of "Irritable Heart. There has been no direct proof up to the present time to substantiate this view. On the contrary, MacGregor[22] makes the statement that this condition is as frequent among Sikh soldiers, who are non-smokers, as among other Indian troops. Lewis[2] has also found, according to the patients' own statements and also from observation, that consumption of tobacco is not inordinate. On the other hand, it is a common experience to find patients who state that smoking, particularly cigarettes, aggravates their symptoms.

Parkinson and Koefod[23] have investigated the influence of cigarette smoking on these patients, and have found that there was an increase in the pulse and respiratory rate, both on the part of the control and the patient, but more so in the latter. They found, also, that cigarette smoking increased the symptoms on exertion in the patients but had little or no effect in the controls. They came to the conclusion that "excessive cigarette smoking is not the essential cause in most cases of 'soldier's heart,' but in our opinion it is an important contributory factor in the breathlessness and precordial pain of many of them."

(*e*) *Occupations.*—Lewis,[2] in his memorandum, makes an exhaustive analysis of the previous occupations of these patients. He found that 57 per cent. were recruited from sedentary occupations, 20 per cent. from moderate, and 23 per cent. from heavy employments. The number recruited from the light or sedentary occupations seems extraordinarily high. The question arises whether these symptoms arose through the patients being unaccustomed to heavy work, or whether they had adopted light employment through preference. The latter appears to be the case in many instances. It is quite common to obtain a voluntary statement from these patients that they had to give up a heavier occupation on account of the symptoms, or that they never attempted more than sedentary work, as they found, as boys, they could not undertake strenuous exertion. The fact is also elicited from a certain number of patients who had always been engaged in sedentary work that they first noticed their symptoms in training; in other words, they were quite ignorant of any inability to accomplish physical exertion until they were called upon to keep up with their more strenuous and hardy comrades.

There is at present no proof that sedentary employment predisposes to this condition, although it may be stated that those employed in such positions constitute a considerable percentage of those so affected.

(*f*) *Constitutional Characteristics.*—It has been forcibly impressed on all those who have worked with these patients that they belong, as a rule, to the "weedy" class. Many exceptions may be cited to this rule, but these almost uniformly consist of those who have been subjected recently to some extraordinarily severe mental or physical strain, such as serious gas poisoning, burial, or infection. Oppenheimer and Rothschild[15] have demonstrated the existence of a constitutional asthenia in a large per cent. of these cases. By this they mean "a relative infirmity or an anomaly in the assemblage of inherent characteristics, both functional and morphologic, which make up the organism."

(*g*) *Strain.*—The influence of severe physical exertion in producing these symptoms appears to be of very minor importance. Cases which give a history of the onset of symptoms dating definitely from some severe strain are comparatively rare. On the other hand, patients frequently date their symptoms from first undertaking some comparatively mild exertion, such as walking, during convalescence from an infection. It would appear that the infection was the primary cause, while the exertion merely elicited the symptoms.

PROPHYLAXIS AND TREATMENT.—Prophylaxis in these cases applies both to recruits and to invalid soldiers, perhaps more to the former than the latter. Taking into consideration the high incidence of this condition in men of sedentary habits and occupation, and the large number who fail during training, it is essential that more reasonable and more tender methods be adopted during the initial training of the recruits. Of course, under the strenuous circumstances of an urgent mobilization this may be altogether impossible. However, even in the most acute situations no good is accomplished by attempting to force the palpably weedy recruit to accomplish hurriedly the same power of physical endurance as the man who has always been accustomed to strenuous labor. No matter how enthusiastic the spirit, often the body is weak; therefore it is necessary to separately train those who fall by the wayside during the early weeks or months of their army career. No good can be accomplished by forcing

them beyond their power of physical endurance; they will be broken, not made. At the same time, it is necessary to observe these men carefully in order that the symptoms may not be exaggerated out of proportion to what the observed signs would warrant.

This more tender method of training was early recognized in regard to the invalided soldier. He was one with experience, a more valuable man, on the whole, than the recruit. His retraining became an easy but steady re-education to full physical powers. The weaker were taken more slowly than the stronger, but all the time a careful scrutiny and firm manner was adopted. The power of physical endurance was tested by practical exercises. This is the clue to the prophylaxis, prognosis, and treatment of these cases. It has become such an important part of this condition that it requires considerable consideration.

Physical Exercise.—It is quite evident from what has been stated already that the condition known as "Irritable Heart" is an exaggeration of the normal. The ordinary individual can accomplish a certain amount of physical work without symptoms, but if they attempt more than this amount they become palpably distressed. The patients act likewise, but the amount of work producing a similar degree of distress is much less than in the normal. That they do not react all in a like degree is most obvious. How, then, may the less affected be differentiated from the more affected, and how may those who are unfit for further military service be recognized.

Early in the work of the Hampstead Military Hospital it became apparent that some method of determining these points was essential. Therefore, a system of physical exercises was adopted. These were modified from the army manual. This served a double purpose. They were already familiar to the man who had been some time in the service, and also formed part of the training of the recruit. Further, they could be continued when the men returned to their depots and battalions, and no change of method or system would be necessary. The particular exercises were chosen so that an easy graduation from one stage to another could be obtained, and they were supplemented by route marches of various lengths, with and without kits. They are here given in detail:

Exercise Table A^{15}

(Fifteen Minutes)

Heels raise, feet close.
Head backward bend.
Hips firm, arms bend, arms upward stretch.
Trunk turning (with feet closed).
Foot sideways place.
Trunk bending sideways.
Trunk forward bend.

Exercise Table B^{15}

(Fifteen Minutes)

Heels raise and knees bend.
Arms sideways stretch, one arm upward, one arm downward stretch.
Trunk turning (feet apart).
Feet close and full open.
Trunk bending sideways.
Slow march.

Exercise Table C^{15}

(Fifteen Minutes)

Heel raising and knee bending quickly.
One arm upward, one arm downward stretch.
Foot placing sideways.
Trunk bending sideways.
Trunk backward bend.
Trunk forward bend.
Slow march.

Exercise Table C^{15}

(Fifteen Minutes—Second Part)

Arms forward bend.
Trunk turning.
Knee raising.
On the hands down.
Quick march.
Knee raising quick mark time.
Slow march.

Exercise Table D^{30}

(Thirty Minutes)

Heels raise, knees bend, arm stretching sideways.
Head backward bend.
Arm swinging upward.
Trunk turning quickly.
Foot placing sideways.
Leg raising forward.
Trunk bending sideways quickly.
Lying on the back down, leg raising.
On the hands down, arms bend.
Trunk forward bend, arm stretching sideways.
Knee raising, quick march.
On alternate feet hop.
Upward jumping.
Slow march.
Arm raising sideways, upward, sideways, downward.

The individual exercises were grouped under the headings A^{15}, B^{15}, C^{15} (first part), C (second part), each of which occupies fifteen minutes, and under D^{30} which occupied thirty minutes. The exercises were taken daily and in favorable instances a patient moved to a higher grade exercise after three or four days. The patient moved from A^{15} to B^{15} to C^{15}, to AB (thirty minutes) to BC (thirty minutes) to C^{30} (both parts), and finally to D^{30}. Thus he passed through seven groups of exercises, in a scale of ascending severity. D^{30} was eventually taken in combination with route marches of four or more miles without pack, with light pack, or in full marching order.[24]

As soon as a patient finished his first day on a new exercise he reported to his medical officer, who noted the symptoms and signs, such as dyspnea, tachycardia, facial expression, pallor, sweating, etc. According to the occurrence or severity of these signs he was continued on the exercise, or reduced for the time being to a milder one. Never has an accident of consequence occurred in any of the cases during the performance of these exercises.[25]

"That a man's observed capacity to accomplish work of a given order is the only dependable test of such capacity would seem self-evident; yet it was our experience that medical officers rely more upon physical signs obtained while the subject was at rest."[22]

If recruits who are palpably deficient in physical

endurance were so handled for a few months, the absolutely unfit could easily be eliminated, the more fit could be temporarily classed in low categories, while the border-line cases, instead of being more or less permanently broken as first-class soldiers, would frequently be "trained" or developed to become capable of a sufficient amount of physical endurance to make them first-class soldiers. This is equally true both of the recruit and of the convalescent. The importance of gradual training cannot be overestimated in the young adult, scarcely past adolescence, who makes up a large part of the potential reserve of man power in any country which has been at war for more than a few years.

There is an important peace-time lesson to be learned from this so-called soldier's disease: namely, the importance of gradual and graduated athletics in our schools and colleges. The number of youths who have been permanently disabled by attempting, without supervision, too strenuous exertion while convalescent from some perhaps paltry infection is undoubtedly great. Likewise if we knew the number of youths who have been permanently disabled by attempting or persisting in games beyond their immediate powers of endurance it would throw a strong sidelight on our present-day rivalry in athletics.[27]

Prophylaxis in "Irritable Heart" of soldiers resolves itself into the question of scientific training of the recruit and the convalescent, while the prognosis "depends upon the observed capacity to accomplish work of a given order."[24]

Besides the method of physical reeducation by graduated exercises, many methods of treatment have been attempted with more or less success.

Occupation.—This constitutes a very important branch of treatment, particularly for those cases in whom the nervous symptoms are prominent. By occupation is not merely meant work of a physical nature; mental work is also of importance. These cases are notoriously introspective, and great benefit results from keeping them interested in some occupation. The whole day should be occupied by various means, games, gardening, walking, indoor and outdoor duties about the hospital or camp. These methods are particularly applicable to the convalescent.

Rest.—It has been shown quite conclusively that rest in bed aggravates the cardiac and respiratory symptoms on exertion.[14] The anoxemia resulting from rapid, shallow breathing is exaggerated by resting in the prone position. Therefore it should be discouraged under all circumstances except during an acute infection, or where the condition of the patient is so severe through tachycardia, dyspnea, or precordial pain as to make it an absolute necessity. When it is imperative on account of these circumstances, the patient should always be kept in the upright or semi-prone position.

Focal Infection.—All sources of focal infection should be diligently sought for and removed. It has been shown that not only are infections the most important etiological cause of this condition, but also that when they occur during the course of the disease they greatly aggravate the existing symptoms.

Digitalis.—Parkinson[25] has made a careful study of the effect of digitalis on the tachycardia found in these cases. He comes to the conclusion "that digitalis scarcely influences the group of patients classified as 'Irritable Heart,' even when the pulse is frequent, and that it is not indicated in this condition."

Oxygen.—Barcroft[20] and his associates have obtained brilliant results from the continuous inhalations of oxygen in cases of gas-poisoning exhibiting the symptoms of "irritable heart." Haldane, Meakins, and Priestley have corroborated these results by the use of oxygen during the sleeping hours only. Unfortunately similar results have not been obtained in cases who date their symptoms from other etiological factors, such as infections.[21] These observations on the proper use of oxygen in cardio-respiratory disorders of function have done a great deal to place the use of this therapeutic measure on a new footing after years of misuse and consequent skepticism.

Conclusion.—Any one who has closely studied this subject of "Irritable Heart" cannot but be impressed by the wide distribution of the condition and the importance it plays in civilian and army life. That it is a definite pathological entity there is no proof; on the contrary, all evidence goes more and more to show that it is a conglomerate collection of functional disturbances producing a more or less identical group of symptoms. Although all cases are similar, they are not identical. In some the respiratory symptoms predominate, in others the cardiac, while in still others the nervous symptoms. It seems probable that this is a disease of function more than of structure, and until such time as perversions of function are investigated independent of structural change, a definite understanding of this syndrome of symptoms may not be arrived at. The key of the situation appears to be hidden in the interrelationship of cardiovascular and respiratory functions, with the nervous and chemical processes which govern them.

Medicolegal Notes.

Harrison Act Held Valid.—On appeal from a conviction for violation of the Harrison Anti-Narcotic Act by the sale of morphine, heroin, and cocaine to persons not producing written orders on forms issued by the Commissioner of Internal Revenue, it was contended that the statute was unconstitutional. It was urged that the purpose of the statute was the suppression of the drug habit, and that it is therefore not a revenue measure, but one of police, within the exclusive province of the states. But it was held by the Circuit Court of Appeals, Eighth Circuit, that the act is valid as a revenue measure, having real relation to the raising of revenue by bringing the traffic in such drugs into the open, and it is immaterial that another purpose of Congress may have been the suppression of the drug habit. It was also urged that there was no evidence that morphine, heroin, and cocaine are derivatives of opium and coca leaves. The court held this to be a matter of which judicial notice may be taken, and no evidence on the subject was necessary. In a sense the question is one of the definition or meaning of words long in common use, about which there is no obscurity, controversy, or dispute, and of which the imperfectly informed can gain complete knowledge by resort to dictionaries within reach of everybody. Had it deemed it necessary, the court might have affirmatively told the jury the nature of the drugs sold by the accused, but instead of doing so, it assumed without question that they were of the kind covered by the statute, as in fact they were. Common knowledge, or the common means of knowledge, of the settled, undisputed things of life, need not always be laid aside on entering a courtroom.

It was held that it was immaterial that the defendant was a physician; his sales not being in the practice of his profession, but as a registered dealer.—Hughes v. United States, 253 Fed. 543.

Expert Testimony as to Value of Physicians' Services—Use of X-rays in Diagnosis.—In an action for $1000 for professional services the defendant sought to recover damages for alleged unskilful treatment. The jury found for the plaintiff and against the defendant on his cross-complaint. On appeal it appeared that the plaintiff was called upon to attend the defendant, whom he found suffering from a fracture of the neck of the femur. At his first visit the plaintiff adjusted the broken part and applied a weight to the limb. A trained nurse was called to attend the case and the plaintiff continued his ministrations during several months, and until the defendant was able to move about on crutches. It was shown that the patient later became able to walk, even without the aid of a cane, at least for short distances. The patient made about eighty-five visits to the defendant. During the time he attended him he was called upon to prescribe for other conditions than the broken bone, to wit, pneumonia and rheumatism. From all of the medical testimony, even that produced by the defendant, it appeared that so far as the fracture was concerned, the results obtained by the plaintiff were better than the average. Under the evidence as presented, it was held that the matter of the value to be placed upon the services rendered by the plaintiff to the defendant was a question exclusively for the jury.

On the cross-examination of one of the expert witnesses, who had testified hypothetically, objection was held properly sustained to a question which assumed facts which did not appear in the evidence, or did not correctly narrate the conditions shown by the hypothetical question, which was the basis of the witness' first answer.

The same witness was asked, on cross-examination, as to whether it was not customary, in cases of the character involved, to take an X-ray picture. Objection to this was sustained. It was held that this ruling could not prejudice the defendant. Concededly the taking of an X-ray picture was only valuable for purposes of diagnosis, and it was clear that the diagnosis made by the plaintiff without the aid of the X-ray was the correct one. Moreover, the matter of the advisability and value of X-ray pictures was fully gone into in the testimony introduced later in the case.

It was also held that where a medical expert testified hypothetically as to the value of medical services, it was within the trial court's discretion to refuse to allow a discussion, possibly lengthy, as to a course of treatment not included within the facts as shown, upon which he based his testimony.

Questions asked of a witness who was the trained nurse who had attended the defendant under the plaintiff's direction all went to the point as to what the witness had observed other physicians do in like cases, or what she considered good or customary treatment. The court did not think that the opinion of the trained nurse was competent evidence to show that the treatment administered by the plaintiff was improper.—MacCoy v. Gage (Cal.), 177 Pac. 296.

Privileged Communications—Limits of Scope.—In an action on a life insurance policy, the testimony of an operating and assistant surgeon at the hospital where the insured died, as to the condition the insured was in at the time of the operation, was held inadmissible under the New York Code Civ. Proc., §834, prohibiting disclosure of professional information by physicians and surgeons. The record of the insured's case, kept by a hospital where he was treated about three months before applying for insurance, was also held properly excluded under the statute. But though the doctor of the hospital where the insured was treated before applying for insurance could not have described the operation, or any condition be observed necessarily disclosed by inspection of the insured's body, he could have testified that at a certain time he performed the operation. In Klein v. Prudential Ins. Co., 221 N. Y. 453, 117 N. E. 942, the court held it was not error to allow a physician to testify that he attended the deceased on a certain day, and that he was sick. And in Patten v. United Life & Acc. Ins. Ass., 133 N. Y. 450. 31 N. E. 342, it was held that a physician could testify that he attended professionally upon the deceased at a given period of time, and how many times he called, and whether daily or hourly; in fact, that the physician attended the deceased in a professional capacity; but that the information concerning which the inquiry is made was necessary to enable him to act in that capacity must be developed in order to lay a foundation for the objection under section 834.—Sparer v. Travelers' Ins. Co., 173 N. Y. Supp. 673.

Basis of Expert Opinion.—A physician in giving evidence as an expert may base his opinion upon his observation and examination of the patient, together with a history of the case as given to him, and such opinion will not be rendered inadmissible in evidence because based partly upon statements made to him by the patient with reference to her condition, symptoms, sensations and feelings when they were made to him, and were necessary to an examination and proper diagnosis and treatment of the patient's injuries. In an action for personal injury, a physician's testimony that from the patient's statements her jump out of a wagon would have been sufficient to produce her miscarriage was not objectionable as invading the jury's province by stating what did in fact cause the miscarriage. Where an injury complained of is of such a character as to require skilled and professional men to determine the cause and extent thereof, the question is one of science and must necessarily be proved by the testimony of skilled professional persons.—Ft. Smith & W. Ry. Co. v Hutchinson, Oklahoma Supreme Court, 175 Pac. 922.

THE PREVENTION OF SCURVY.

DURING the past few years scurvy has been more or less common among the armies in the near and far East. In consequence, the etiology and treatment of the condition have been studied quite closely. Of course, it has been known for some time to be a deficiency disease, that is a disease due to a deficiency or lack of vitamine content in the diet, but this fact has been strongly emphasized by the investigations made in Mesopotamia and elsewhere. Also dietectic treatment has further clinched the point that scurvy is a deficiency disease. The Food Committee of the British Royal Society issued a short time ago the following conclusions as to scurvy, based on investigations made at the Lister Institute, London: (1) Scurvy, like beriberi, is a "deficiency disease" and is due to the continued consumption of food lacking in an accessory food substance or vitamine. (2) This vitamine is contained in a number of fresh foods, in largest amounts in oranges, lemons, and fresh green vegetables, in considerable amounts in roots and tubers, such as turnips, potatoes, etc. It is deficient in all dried and preserved foods. (3) It is destroyed by prolonged heating. Thus potatoes in stews would be devoid of vitamine, but if boiled rapidly will still contain a small quantity. Alkalies rapidly destroy antiscorbutic properties. Soda should not, therefore, be added to water in which vegetables are soaked or boiled. (4) Before the onset of definite symptoms of scurvy there is a period of debility and weakened resistance to disease. Cases of debility in any body of troops without sufficient cause should at once direct attention to the diet. (5) West Indian lime juice as ordinarily prepared is useless. Fresh limes have an antiscorbutic quality but their efficiency is only one-fourth that of lemons. Orange juice is as effective as lemon juice. (6) Potatoes and root vegetables have a distinct value in the prevention of scurvy, much less, however, than green vegetables or fresh fruit juices. (7) Pulses—beans, peas, and lentils—in the dried condition have no antiscorbutic properties. If, however, the dried seeds are soaked in water and allowed to germinate for a short period, they develop the antiscorbutic vitamine. At the same time these pulses are also rich in the vitamine which prevents beriberi, and are, moreover, valuable foods. (8) The antiscorbutic value of fresh meat is very low in comparison with fresh vegetables and fruit. Tinned and preserved meats possess no antiscorbutic value. Frozen meat, while more valuable than preserved meat, must be considered inferior to freshly killed meat. (9) The destruction of antiscorbutic properties of foods during the process of cooking depends upon the time of cooking and temperature employed. All foods, especially vegetables, should be cooked in as short a time as possible at boiling point. Slow methods of cooking, such as stewing or simmering below boiling point, should be avoided. Potatoes should be plunged into boiling water and boiling continued for twenty or thirty minutes after boiling point had again been reached. Frozen meat should be roasted when practicable.

These findings go to show that views as to the value of the various foods from the nutritive standpoint have changed greatly within the past ten or twenty years. The vitamine content of food must not be greatly impaired or nutrition will not only be unsatisfactory, but beyond a certain point pathological conditions will be produced. Meat has been shown to be in many respects, and especially so far as vitamines are concerned, inferior to other foods which not long ago used to be regarded with thinly veiled contempt. The pulses, either fresh or germinating, have been elevated to a high position among the food products and are as economical as they are nutritious. The report from which quotations have been made gives some useful advice as to cooking, an art concerning which there is a great deal of ignorance, and particularly with regard to cooking in such a manner as to preserve as much as possible the nutritive properties of the food. Lastly, it was shown that canned and dried foods do not contain the amount of nourishment which is contained in fresh foods, and that so far as vitamine content is concerned they are useless. Our ideas as to food must evidently undergo a great deal of revision from all points of view.

INDURATIONS OF THE CORPORA CAVERNOSA.

CORBINEAU in a synthetic review of this subject published in the *Journal d'urologie* for May has collected notes of 189 cases reported during the period 1743-1918. The subject had previously been summed up by Zislin in 1911, this author having incorporated many cases probably not previously published. But few scattered cases were on record up to 1875 at which period Van Buren published notes of 5. During the 80's many cases came to light and Maurice alone reported 17, Tuffier 10, and Verneuil 6. Since that epoch several cases have come to light annually but it is probable that the real total is much greater than appears from this article. The number is certainly large enough to admit of an instructive analysis.

In the first place there is no doubt of the rarity of this affection for Ricord with his great experi-

ence saw about a score of cases only. It should be stated here that many cases reported under this head were doubtless examples of wrong diagnosis and all such have been left out of the tabulation. An affection of elderly men, it is yet seen at times in early adult life. The most common seat is the anterior third of the penis but quite a number appear at the root and sometimes the entire organ is involved. In regard to cause and nature the author gives the following: Inflammatory or gonorrheal, syphilitic, traumatic, diathetic, and unknown. Under diathetic he includes all such constitutional factors as diabetic, gouty, rheumatic, tuberculous. The frequency of each type has varied much with the material and two or more alleged factors may coexist in a case. The author's combined material shows that traumatism is not a common cause while the diathetic or metabolic factors are very numerous, no less than 66 possessing such a factor. Tuberculosis plays a negligible rôle. No less than 55 of the patients had had gonorrhea alone or with other factors, while about a score had had syphilis. The number of cases without data and those with negative data totaled 37.

Such numerous antecedents serve to confuse the pathogeny, and we have theories without end which seek to connect causes and effects. This vagueness is offset by the vividness of the symptoms, for the condition simulates in some ways chordee, the organ being bent and painful during erection and emission. Coitus is impossible with marked deviation, while in moderate degrees the ligneous hardness of the organ is extremely burdensome for the woman. The act of erection may be very slow and deliberate. This condition is capable of causing some of the worst cases of sexual neuroses and hypochondria.

THE PROPHYLACTIC OR CURATIVE VALUE OF BACTERIAL VACCINES.

The estimation of the value of bacterial vaccines generally is not particularly definite. This has given rise to the view that vaccine therapy is, as a rule, not to be greatly depended upon. While it is true that some of the results of prophylactic and curative treatment by means of vaccines are unsatisfactory, the mode of treatment should not be wholly condemned on this account. A good deal of the confusion which exists as to value of vaccines is because not infrequently the data upon which conclusions are based will not bear close investigation. Dr. G. W. McCoy, director of the Hygienic Laboratory, U. S. Public Health Service, points out in Public Health Reports, May 30, 1919, some of the pitfalls in determining the prophylactic or curative value of bacterial vaccines which are in the path of those who employ them.

According to McCoy, the most common source of error is that due to the employment of a vaccine in an institution or in a group not in an institution, after cases of the disease have appeared. Influenza develops among the persons in a given group, prophylactic vaccinations are undertaken more or less promptly, and no cases may occur after the inoculations have been completed. However, closer examination generally reveals the fact that so large a proportion of the personnel involved has developed the disease before the vaccinations were done that in all probability the remainder would not sicken whether vaccinated or not. Thus the figures lose their significance. A second source of error consists in vaccinating all persons in a group and interpreting failure of the disease to appear as evidence of protection. It only requires a study of the data with regard to certain institutions where without vaccinations the disease has been excluded, or has spread but slightly, to realize how fallacious such arguments are. The third, and in McCoy's opinion the most common, pitfall is the drawing of conclusions from meager data.

He therefore thinks that many of the cases of cure, especially perhaps in influenza and pneumonia, attributed to the use of vaccines should be received with a certain amount of reserve, and should not be accepted at their face value until convincing proof has been given that the results were really owing to vaccination.

According to McCoy, the sole way in which promptly acceptable evidence of the value of a bacterial vaccine can be secured is by the vaccination of only a portion of the individuals in a large group, holding the remainder as controls; age, sex, and conditions of exposure being the same in the two groups. On the other hand, a vaccine should not be condemned unless properly controlled, and unless it has failed to show protective value when sufficient time has elapsed after the inoculation to make it reasonably likely that any immunity which may develop will have had an opportunity to do so.

Vaccine therapy has a great future, but it will not be helped by making extravagant claims for it. Its use should be conducted upon a strictly scientific basis, and cases should be so thoroughly investigated that there can be no doubt as to the results. Employed in an unscientific manner, or in a hit-or-miss way, the outcome is uncertain, and in the long run the use of vaccination by such methods will not tend to create confidence in it, either as a prophylactic or as a cure.

THE COMMON INTERESTS OF THE MEDICAL PROFESSION AND THE COMMUNITY.

There is to be a Ministry of Health in Great Britain, and it is feared—and this fear is not without cause—that in the framing and in the carrying out of a bill to appoint such a ministry the medical profession will not have the voice and the power which are justly their due. The tendency of the labor classes in Great Britain is to depreciate the medical profession, to regard it as of the privileged class, and to endeavor to shear its influence in every way. It seems that if the labor party has its will the medical man will lose his independence and become a servant of the people. If the framing of the bill is left wholly in the hands

of the politicians it is more or less certain that such will be the result. The politician will kow tow to the strongest party. The medical profession is almost negligible in politics, and thus the outlook for the British medical profession is not promising, and it is realized that if its members are to be saved from the fate which appears to threaten them they must organize and fight the politicians with their own weapons.

A conference of medical men was held recenly in London for the purpose of promoting such an organization. Among the speakers was Dr. Arthur Latham, who in the course of his remarks said that the medical profession would never have political power until the public was on the side of the medical man, and that would happen when the public was approached through a body which was recognized as one looking after the community rather than after the doctor. And this was the right order, for the interests of the doctor would be cared for if the interests of the community were met. The mistake the medical profession had made in the past was that they had not led the public to understand that the interests of the profession were wrapped up in the interests of the community.

Of course, all this is very true, and the public and medical men must be in harmony or there will be little hope for a successful national department of health. If the conditions of service are unfair, the doctor will be discontented, the work will be bad, and the best brains will not be attracted to the medical profession. It is obvious that the public and medical men must pull together or no workable scheme for a department of health will be forthcoming; or, if forthcoming, will be unsatisfactory and will fail when put into practice.

There is little doubt that in this country also a national department of health is coming, and while the conditions here and in England differ there is enough similarity to make the experiences through which the profession of that country is now going instructive. In both countries the medical profession wields little or no political influence, and without organization is at the mercy of the politicians. Consequently it would appear that the wisest procedure on the part of the medical professions of the English-speaking lands on both sides of the Atlantic will be to organize promptly so as to defend their own interests and at the same time being recognized as strictly fair to the community.

The "Signe du Tiroir" of the French.

Mouchet recently described this phenomenon, as named by Rocher of Bordeaux, at a meeting of the Paris Surgical Society (*La Presse Médicale*, April 10). In four cases of young people in Rocher's service who sprained the knee certain troubles long persisted, including a limp, atrophy of the quadriceps, creaking sounds on motion, fatigue after walking, occasional appearance of fluid in the joint, etc. In these cases there was suspicion of chronic arthritis and also of simulation. In cases of this type Rocher calls attention to a peculiar sign which had indeed been seen by others but not studied critically. It is an induced phenomenon in which the subject lies supine on the table to obtain complete relaxation. He is now made to flex the thigh on the trunk and the knee on the thigh, the degree in the latter case being from 90 to 110, obtained by placing the sole flat on the table. The palms of the hands are now placed against the posterior upper third of the calf and the tibial surfaces pushed or slid along the femoral surfaces of the joint, as if one were closing the drawer of a commode. If the crucial ligaments have ever sustained an injury a veritable subluxation is produced from behind forward. The same gliding movement can be produced by the muscular contraction of the patient, both in the sitting and standing postures. All he has to do is to flex slightly his leg. The gliding may be attended by a slight dry sound and the displacement in the joint is clearly shown in the radiograph. Mouchet, who reported the work of Rocher to the Society, has by experiments on the cadaver in which the crucial ligaments were divided corroborated the finds of the latter. Hence the forward displacement of the tibia on the condyles when the joint is flexed, denotes injury to the crucial ligaments, either both or the anterior only. At the same time slight torsion from without inward occurs, the nature of which has not been fully decided but which is expressed by a slight prominence at the rear of the joint. This latter phenomenon is inconstant and in the absence of illustrations is not readily visualized.

News of the Week.

Bronx County Medical Society on Health Insurance.—At a recent monthly meeting of the Bronx County Medical Society resolutions were passed stating that it was the consensus of opinion of the members of the society that every member pledge himself not to act under any Health Insurance Act which might be passed but which had not the support of the society. Cards have been sent to each member of the society requesting his signature to these resolutions.

Bureau of Narcotic Research.—The constantly widening breach between physicians and health authorities as to the true definition of drug addiction and the best method of combating the evil have created a difficult situation in New York State, which has emphasized the need of an intelligent study of the situation. To meet this need the Bureau of Narcotic Research has been established at 47 West Forty-second Street. The purposes of the bureau are to study the situation, keep abreast of the times by collecting all data, remedial and legislative, bearing on the problem, and to provide the machinery by which this information can be disseminated through proper channels. The bureau is under the direction of A. R. Parkhurst, and will be at all times at the disposal of the physician, the medical press, and the decent addict. On file are all the treatises on drug addiction prepared by authorities on this subject. Hundreds of histories of addicts are also on the files, all of which have been checked up to the minutest detail and found to be truthful. Advice is given to the addict as to the best

means of obtaining treatment and not a few addicts who are penniless are sent to the Public Addiction Clinic conducted by the Board of Health. The energies of the Bureau for the time being will be concentrated on propaganda of an educational nature with the hope of arousing the public to the necessity of studying narcotic drug addiction as a disease and not as a vice.

Birth Statistics in United States for 1917.—The Bureau of Census, Washington, D. C., has issued a preliminary report presenting statistics in the birth registration area of the United States which shows that 1,353,792 infants were born alive in 1917, representing a birth rate of 24.6 per 1,000 of the population. The total number of deaths in the same area was 776,222, or 14.1 per 1,000. The births exceeded the deaths by 74.4 per cent. The mortality rate for infants under one year of age averaged 93.8 per 1,000 living births. The birth registration area has grown rapidly, comprising, in 1917, the six New England States, Indiana, Kansas, Kentucky, Maryland, Michigan, Minnesota, New York, North Carolina, Ohio, Pennsylvania, Utah, Virginia, Washington, Wisconsin, and the District of Columbia. This includes about 53 per cent. of the estimated population of the United States. The birth rate for the entire registration area fell below that for 1916 by two-tenths of one per 1,000 population; the death rate was less by six-tenths of one per 1,000 than in 1916. Thus the excess of the birth rate over the death rate for 1917, which amounted to 10.5 per 1,000, was somewhat greater than the corresponding excess for 1916, 10.1 per 1,000, although it fell slightly below that for 1915. If the birth and death rates of any one of these years were to remain unchanged, and if no migration were to take place to or from the area to which they relate, its population would increase at the rate of slightly more than 10 per cent. in a decade. This would be about one-half the rate—21 per cent.—by which the entire population of the United States increased between 1900 and 1910. The infant mortality rate in the different states of the registration area ranged from 67.4 for Minnesota to 119.9 for Maryland. For the white population separately the lowest and the highest rates were 66.3 for Washington and 109.5 for New Hampshire. A comparison of the mortality rates on the basis of the nationality of the mother shows a minimum of 66.2 per 1,000 births for infants whose mothers were born in Denmark, Norway, and Sweden, and the maximum of 172.6 for infants with mothers born in Poland, while for Negro children the rate was 148.6. The plural births were a little more than 2 per cent. of the total number. From the data available as to previous births in the families reporting births for 1917, it appeared that there was an average of very nearly three living children in each family in which a birth took place in 1917.

Medical Society Elections.—The AMERICAN MEDICAL EDITORS ASSOCIATION, at its Golden Anniversary meeting, held in Atlantic City June 9 and 10 under the presidency of Dr. George W. Kosmak, of New York, elected the following officers for the ensuing year: *President*, Dr. Seale Harris, Birmingham, Ala.; *First Vice-President*, Dr. Franklin H. Martin, Chicago; *Second Vice-President*, Dr. H. S. Baketel, New York; *Secretary*, Dr. Joseph MacDonald, Jr.; *Executive Committee*, Dr. George W. Kosmak, New York; Dr. E. H. Lewis, New York; Dr. D. S. Fairchild, Clinton, Ia.

THE WESTERN ELECTROTHERAPEUTIC ASSOCIATION was organized in Kansas City, on May 8, for the purpose of cultivating and promoting knowledge in whatever relates to the application of electricity and other physical measures in medicine and surgery. The officers for 1919-1920 are: *President*, B. B. Grover, Colorado Springs, Colo.; *First Vice-President*, W. P. Grimes, Kansas City, Mo.; *Second Vice-President*, Theo. F. Clark, Eldorado, Kan.; *Secretary*, Chas. Wood Fassett, Kansas City, Mo.; *Treasurer*, Chas. Keown, Independence, Mo.; *Registrar*, E. A. Nelson, Phillipsburg, Kans. The next meeting will be held at Kansas City, Mo., May 18-20, 1920.

The AMERICAN PSYCHOANALYTIC ASSOCIATION, at its ninth annual meeting, held at Atlantic City, June 20, 1919, under the chairmanship of Dr. Smith Ely Jelliffe, of New York, elected the following officers: *President*, Dr. A. A. Brill; *Vice-President*, Dr. H. W. Frink; *Secretary and Treasurer*, Dr. W. A. White; *Council*, Drs. Smith Ely Jelliffe, G. L. Taneyhill, and C. P. Oberndorf.

The ARKANSAS MEDICAL SOCIETY, at its annual meeting, held in Little Rock, May 22, 1919, elected the following officers for the ensuing year: *President*, Dr. George S. Brown, Conway; *First Vice-President*, Dr. C. E. Kitchens, DeQueen; *Second Vice-President*, Dr. A. L. Carmichael, Little Rock; *Third Vice-President*, Dr. R. E. Cooksey, Magnolia; *Secretary*, Dr. C. P. Meriwether, Little Rock; *Treasurer*, Dr. W. R. Bathurst, Little Rock.

The FLORIDA STATE MEDICAL ASSOCIATION, at its annual meeting, held in Jacksonville, May 23, 1919, elected the following officers for the ensuing year: *President*, Dr. William E. Ross, Jacksonville; *First Vice-President*, Dr. H. C. Babcock, Miami; *Second Vice-President*, Dr. J. A. Simmons, DeLand; *Third Vice-President*, Dr. W. D. Davis, DeLand; *Secretary*, Dr. Graham E. Henson, Jacksonville.

THE FRISCO SYSTEM MEDICAL ASSOCIATION, at its eighteenth annual convention, held in Springfield, Mo., May 12, elected the following officers for the ensuing year: *President*, Dr. C. M. Lutterloh, Jonesboro; *First Vice-President*, Dr. C. N. Cargyle, Bentonville; *Second Vice-President*, Dr. Miles Duncan, Dallas, Tex.; *Secretary-Treasurer*, Dr. A. R. Woolsey, St. Louis.

THE VIRGINIA HOMEOPATHIC MEDICAL SOCIETY, at its annual meeting, held in Petersburg, elected the following officers for the ensuing year: *President*, Dr. R. S. Faris, Richmond; *Vice-President*, Dr. H. B. Baker, Richmond; *Secretary-Treasurer*, Dr. G. W. Johnson, Danville.

THE MISSISSIPPI STATE MEDICAL ASSOCIATION, at its annual meeting, held in Hattiesburg, May 14, 1919, elected the fellowing officers for the ensuing year: *President*, Dr. F. J. Underwood, Aberdeen; *Secretary*, Dr. I. M. Dye, Clarksdale; *Treasurer*, Dr. J. M. Buchanan.

Commencements.—At the ninety-fourth annual commencement of Jefferson Medical College on June 8 the degree of Doctor of Medicine was con-

ferred on 142 graduates. Surgeon General Marritte W. Ireland, of the class of 1891, delivered an address on "The Progress of Medicine in the Twentieth Century." The degree of Doctor of Laws was conferred upon Dr. Ireland and the degree of Bachelor of Science on Dr. Duncan L. Despard.

At the commencement exercises of Hahnemann Medical College of Pennsylvania held at Philadelphia on June 12 there were 25 graduates. It was announced that in the future women would be for the first time admitted as students in the college.

At the sixty-ninth annual commencement of the Woman's Medical College of Pennsylvania held at Philadelphia on June 18 there were 78 graduates.

At the annual commencement of the University of Pennsylvania held at Philadelphia on June 18, there were 1 2 graduates in medicine and General Leonard Wood delivered an address. The degree of Doctor of Laws was conferred upon Dr. Edward Martin, Pennsylvania State Commissioner of Health and the degree of Doctor of Science on Dr. Arthur Hopewell Smith.

The graduation exercises of the Kansas City University of Physicians and Surgeons were held on June 2, at which time the degree of Doctor of Medicine was conferred upon 64 students by Dr. A. M. Wilson, Dean of the University.

At the twentieth commencement of the Cornell University Medical College in New York recently medical degrees were conferred on 29 men and women. Among the prizes were two awarded for the first time this year. These were prizes in gynecology in memory of the late Dr. William Metcalfe Polk. The graduation address was delivered by Dr. Edward L. Keyes, Jr.

Charitable Bequests.—By the will of the late Isabel McLeod Brewster the sum of $500 is bequeathed to the Germantown Hospital and Dispensary of Philadelphia.

By the will of the late Simon B. Fleisher of Philadelphia the sum of $9,000 is bequeathed to the Hospital of that city.

By the will of the late Robert Ralston Stewart of Philadelphia the sum of $10,000 is bequeathed to the Pennsylvania Hospital.

By the will of the late Marcella Ennis of Philadelphia the sum of $1,000 is bequeathed to St. Joseph's Hospital.

By the will of the late Dr. J. Ewing Mears of Philadelphia the sum of $100,000 is bequeathed to Harvard University, for the study of methods directed to the reform and cure of criminals and mental defectives by surgical means; the sum of $5,000 to Jefferson Medical College, for a free scholarship; $',000 to the Rush Hospital for Consumption and Allied Diseases, for free beds in memory of Frances B. Tyson; $2,000 to the Pennsylvania Training School for Feebleminded Children at Elwyn, Pa.

By the will of the late Harriet Blanchard of Philadelphia bequests are made as follows: Protestant Episcopal Hospital, $200,000; Pennsylvania Hospital, $200,000; University of Pennsylvania, $100,000; Hospital of the University of Pennsylvania, $100,000; Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases, $100,000; Woman's Hospital, $100,000; Children's Hospital, $100,000; Polyclinic Hospital, $50,000; Pennsylvania Training School for Feebleminded Children, $25,000; Jefferson Hospital, $10,000.

Taunton Doctors Raise Fees.—The physicians of Taunton, R. I., have voted to raise their schedule of fees. House calls have been raised from $2 to $3, with $4 for visits between 6 and 10 o'clock in the evening, and $5 from 10 at night to 7 in the morning. Office calls will be $2 and telephone calls will be charged as office calls. The Taunton doctors claim that they are compelled to take this step to meet the increased cost of living.

Columbia University Plans New System of Physical Education.—A new system of physical education, revolutionizing methods of caring for the health of college students, has been adopted by Columbia University. Medical surveillance will be extended to the student from the day he enters college until he receives his diploma. The idea will not be to bring every man up to a fixed standard but to perfect him in his own standard. Records similar to those of the army draft boards will be kept. When physical defects appear they will be corrected, with the purpose of turning out men 100 per cent. perfect physically as well as mentally. One aim is to teach every graduate at least two outdoor and indoor sports, so that when he leaves college he will have a basis for relaxation and play. The plan was devised and perfected by Dean Herbert E. Hawkes, Dr. W. H. McCastline and Dr. George L. Meylan. Plans have been made to care for students showing malnutrition, and a restaurant in connection with the college will supply food properly balanced and special diets. Efforts will also be made to give each student a knowledge of his own physical assets, limitations, and peculiar tendencies, and he will be taught that health in the middle and later periods of life is greatly dependent upon a proper understanding of one's own physical make-up.

Obituary Notes.—Dr. JAMES W. SNOWBALL died at Atlantic City, N. J., on May 16 at the age of 54 years. He was graduated from Jefferson Medical College in the class of 1891. He was a member of the Atlantic County Medical Society, the New Jersey State Medical Society, and the American Medical Association.

Dr. VALENTINE J. BOLD died at Philadelphia, on May 21, at the age of 50 years. He was graduated from Jefferson Medical College in the class of 1890.

Dr. CAROLINE V. STILL ANDERSON died at Philadelphia on June 3 of apoplexy at the age of 70 years. She was graduated from the Woman's Medical College of Pennsylvania in the class of 1878.

Dr. HIRAM L. LUTZ died at the University Hospital, Philadelphia, on June 8 at the age of 40 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1900. He was a member of the Philadelphia County Medical Society, the West Philadelphia Medical Society, the Philadelphia Medical Club, the Medical Society of the State of Pennsylvania, and the American Medical Association.

Dr. WILLIAM AUGUSTUS BURNS died of heart disease at Philadelphia on June 8 at the age of 75 years. He was graduated from the medical department of the University of Pennsylvania in 1869.

Correspondence.

LUNG VENTILATION AND ARTIFICIAL RESPIRATION.

To the Editor of the Medical Record:

Sir:—Having recently seen the paper "History and Analysis of the Methods of Resuscitation" by S. J. Meltzer in your journal of July 7, 1917, I find the investigations performed by me in collaboration with Wollin and Nilsson criticised in a manner that is not correct. It is stated that we made experiments on the lung ventilation of man during artificial respiration in apnea, and it is said that "the apnea was brought on by a small series of deep respirations." In contrast to us, Henderson is said to have made experiments on students "who experienced, after overventilating their lungs by two or three minutes of voluntary forced respiration, a lack of desire to breathe (apnea)."

Now, in our publication (*Skand. Arch. f. Physiol.*, 29) it is explicitly stated that there probably can have been no satisfactory apnea in older experiments, and mentioned that our subjects in all experiments in question were breathing maximal (with a frequency of 40 to 60 times and a ventilation from 50 to 78 L.) during one minute and thus obtained an apnea of 85 to 92 seconds on an average. The apnea in Henderson's experiments lasted 40 to 80 seconds.

At the same time I take the liberty of pointing out that it seems to be chronologically incorrect when it is said in the official reports of the commissions on resuscitation from electric shock and from mine gases, respectively, that their results have been confirmed by us. Our publication on lung ventilation by artificial respiration in man being older, was accordingly cited in both the reports, and on several points in much detail, and it seems to me, therefore, that our results were rather confirmed by the commissions than the reverse. It was also stated in a letter to one of us from Haldane that he could confirm our conclusions.

G. Liljestrand, M.D.

Tomtegatan 19A, Stockholm.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, May 29, 1919.

The Medical Services Bill.—The bill for the creation of a Ministry of Health has now received consideration and approval—as far as approval can be given to matters so much in embryo that their real development can only be guessed at—in both Houses of Parliament, where also consideration has been given to representations made by the big medical corporations and companies. It may be taken for granted, therefore, that the bill in the shape which it now possesses will be placed on the statute book as an act at an early date. The scope of this bill, it will be remembered, is mainly the rearrangement of State activities as far as they relate to medicine; the abolition of overlapping so effected will bring into a coordinated whole the activities exercised by the Local Government Board, the National Insurance Commissions, the Board of Education, and in a minor degree the Statistical Bureau at Somerset House, the Foreign Office, the Privy Council, and certain other state departments having under their ægis some sort of medical dispensation and patronage. That is what the bill does; but it does not either institute a State service of medicine as such, nor does it take over the voluntary hospitals and make of their staffs salaried servants of the state.

A corollary of the bill is therefore immediately required to deal directly with the position of the medical practitioner under the act, for while the whole spirit of the new legislation is to give full play to the growing interest manifested by the public in medicine, it is obvious that the public can only enjoy a good medical service if the medical practitioners under that service are treated with proper consideration in the matters of time given and salaries or remuneration received. In the House of Commons, on Wednesday last, Dr. Addison announced that he was already far advanced on a second stage of the Ministry of Health proposals, and that the result should be shown in a Medical Services Bill which he intends to introduce in the House of Commons with promptitude. The underlying purpose of the Medical Services Bill will be to deal with the problems for the solution of which the establishment of a state medical service has been freely urged in certain quarters, though no one familiar with the problems involved expects or desires any transformation of the whole medical profession under a regimented scheme. During the debates upon the Ministry of Health Bill there was ample discussion of the necessity for transferring at an early date to the new ministry the medical side of the Poor law. This is one of the questions which will certainly be tackled in the forthcoming measure, and our readers know well that reforms in this direction are overdue. The Poor-law authorities have been sorely tried, hardly worked, and unjustly abused, but all who know wherein lie the real problems of medicine see that it is high time to relieve the Poor-law authorities of such responsibilities as the provision of institutional treatment for the sick and infirm and for maternity cases. The Ministry of Health Bill will possibly become law before Whitsuntide, and there is a strong desire at the Local Government Board to proceed with its corollaries as quickly as possible. Dr. Addison has stated that he will put his proposals regarding medical services before the Medical Advisory Committee before formulating them in the shape of a bill, and no doubt he will thus receive a great deal of assistance in his effort to meet admitted difficulties for which a plethora of remedies have been suggested, none of which has escaped criticism.

It will be seen that much turns upon the constitution of the Medical Advisory Committee, and it will be recognized also that it is proposed to use this committee in a most practical manner for the good of the medical profession. The rearrangement of functions among the great government departments can well be left to those who have great departmental experiences, and in Sir George Newman, lately the principal medical officer to the Board of Education, and Sir Robert Morant, the chairman of the Joint Committee of National Insurance Commissions, we have two officials, now formally designated for executive charge of the Ministry of Health, who after high trial have been found eminently successful in bureaus where medical and public in-

terests have most closely interdigitated. But the executive of the Ministry of Health will require also information, instruction, and assistance in making effective the general powers for good of the medical profession as the actual executants of the health policy of the measure. Here it is that a properly chosen medical advisory committee, having a statutory position under the parent legislation, can advise as to the shape which a medical services bill should take, so as to place at the disposal of the public the services of the general practitioner with the best chances of benefit to the public and simultaneously under conditions fair to the medical men.

It is not difficult to guess the line which the proposed legislation under a medical services bill will take. The general policy will be one of decentralization of medical activities and the erection of numerous health centers proportionate to the needs of local populations. While it is understood that the great general hospitals, with their medical schools attached, will remain, at any rate for the present, upon their historic and charitable basis, the numerous infirmaries at present working under the Poor law will be elevated to their proper position as the seats of institutional treatment for the sick and infirm and maternity cases. Each of these hospitals will then become a local center for postgraduate medical education and for consultative medical opinion, as well as a focus for the institutional treatment of the sick. The general practitioners in each locality will look to the local hospital for assistance in special medical and surgical cases and for information on various pathological problems. The officers will have to receive salaries, settled on whole-time or half-time basis, according to circumstances.

Vital Statistics at the Zenith of the War.—The annual report of the Registrar General for 1917 has just been issued. Various statistical items with reference to the increase and decrease of populations, and the variations in birth, marriage, and death rates of epidemics, and so on, have all been issued from time to time during 1918—or at any rate the facts have emerged from the publication of separate figures out of which the general summary has been constituted—but the annual report is the considered report and scientific statement showing the net results to Great Britain and Ireland at the time when the war had been in full and disastrous swing for nearly three and a half years. The births registered 117,000 fewer than the previous year and about 210,000 less than were registered in 1914, which may be regarded as the last year unaffected by war conditions. But the birth rate, 17.8 per thousand living, was the lowest ever recorded, the total fall between 1914-1917 inclusive being six per thousand, or just over 25 per cent. The decrease in illegitimate births was more than proportionate, affording thereby direct contradiction of those who prophesied that the circumstances of war would inevitably lead to a vast wave of immorality, and it should be remembered that some of these prophets invented facts to tally with their Chabandism.

The birth rate looks bad, but the death rate of 1917 puts a different complexion upon the position. The civilian death rate, 14.4 per thousand living, at all ages, was actually lower than the average rate of the last ten years of peace experience, 1905-1914. This figure again has its moral, for it proves that despite the depletion of medical service at the height of the war, and despite the difficulties under which public health administration was carried on, the medical profession at home rose to the emergency, and kept civilian health at a good standard. Indeed, a remarkable feature of the year 1917 is the extraordinary low death rate of children under five years, the rate being only about half that prevalent in the concluding decade of the previous century. The high death rate of civilian males bears the obvious explanation that they included among the civilians those men who had been invalided out of the forces and were thus deprived from military circumstances of the statistical assistance of the mass of healthy men serving with the army and navy.

The causes of death, as statistically arranged, present both good and bad features. The year concerned was marked by no influenza epidemic and at the same time a decrease was registered in deaths from enteric fever, scarlet fever and diphtheria. The figures for scarlet fever were the lowest on record, but on the other hand tuberculous disease in the aggregate accounted for the death of more than 2000 persons in excess of 1916. The serious increase in tuberculous mortality is most marked in the ages of 5 to 25, and the incidence among the elders of these young people has been determined possibly by factory conditions, while among the younger it was due to dietary changes. Another factor in the increase of tuberculous deaths is alluded to by the Registrar General as a possible one—namely the overcrowding of lunatic asylums. This overcrowding did not follow upon any marked increase in lunacy but was due to the fact that several of the large lunatic asylums were vacated by their customary inmates, and the buildings being devoted to military purposes the patients were billeted in the remaining institutions. There is a notable increase in deaths from malignant disease, bringing forward again the eternal question: Do modern conditions of life conduce to cancer, or has the perfection of medical science led to the detection of cases of malignant disease which in former times remained undiagnosed? The answer to the latter half of the question is obviously "yes," but unfortunately that does not enable us to answer the first part of the question with an equally obvious "no."

Death of Dr. Luxmoore Drew.—Dr. Clifford Luxmoore Drew, whose death took place last week, was widely known and deservedly popular in medical and legal circles as Coroner for the Western Division of London. Born in India during the famous mutiny, he was educated at Aberdeen, of which University he was a medical graduate. Later, taking up a legal course of training in London, he entered the Middle Temple, became a barrister-at-law, and obtained, with the double qualification, the coveted post of a metropolitan coroner. Here he was an unqualified success, his ability, fairness and courtesy winning him universal esteem. Some years before his death he had the honor of serving as President of the Coroners' Society of England and Wales.

LETTER FROM GENEVA.

(From Our Own Correspondent.)

GENEVA, April 26, 1919.

Effect of War on the Birth-rate.—A society in Copenhagen is stated to be studying the effects of the war on the population, and the German newspapers have published results that have been obtained in their country. These contain one very curious fact which unquestionably requires confirmation. It is stated that for every 1,000 births of males there have been 1,086 female births instead of the normal 1,024. Nothing is known with certainty as to the conditions that determine sex in the human species, but there is quite a large amount of evidence in support of the generalization that during wars and famines, when the conditions are generally adverse, especially with regard to nutrition, the proportion of male relative to female births increases. If there is any foundation for this generalization, then we must conclude either that the figures are wrong, or that Germany was mighty well nourished during the war, or else that some entirely aberrant influence was at work.—

Typhus Fever.—I am in a position today to give you some authentic data relating to typhus fever in Europe since the latter part of 1918. As you know, severe epidemic typhus fever occurred upon several occasions during the war. In 1915, particularly, the epidemic in Serbia caused considerable ravage, to such an extent that the Allied Powers were obliged to combine their efforts in order to suppress the disease. On the other hand, there were an enormous number of victims of typhus in Germany in 1915, among the prisoners of war, particularly at the camps of Cassel and Langensalza, and this has cast an everlasting discredit on the German medical profession on account of the brutal actions and cowardice of both the military and civilian medical men. In the prison camp at Wittenberg, also, the cowardly medical officers ran away, leaving the care of the sick to the British medical officers detained illegally in the camp.

Now, although there was cause for surprise when the disease first appeared and spread, we possess to-day the necessary means for stamping out the affection, and it might have been expected that any menace from it would remain vain. But the conditions of order and rigorous discipline requisite for properly carrying out the necessary prophylactic measures are far from being the same in the present conditions that they were before the cessation of hostilities. Therefore, a recrudescence of the scourge has ensued in eastern Europe, and testimony coming from every direction, and from authoritative sources, is quite enough to cause serious disquiet to the populations of central Europe, who now perceive that they will be the first to be attacked. The following figures are certainly not of the kind to be looked upon lightly.

At Moscow, 1,000 new cases of typhus have been of late declared weekly; in the Ukraine an average of 10 cases of typhus per village in the Dniester region has been computed, making a total of 12,000 cases; in the district of Warsaw there have been 800 cases weekly. The data collected by the delegates of the International Committee of the Geneva Red Cross, who visited the hospitals of Poland, the Ukraine, and in Yougo-Slavia, partially confirm these reports. Holuby and Powiorsk, near Warsaw, have been mentioned as particularly active foci of the disease. The more the East is approached the greater become the numbers of cases.

At Bielostok, on Feb. 22, 1919, there were 200 typhus cases, only 22 of which were in a plague hospital, the remainder being scattered in houses throughout the city. At Grodno, on the same date, 500 cases was the rough estimate, 44 of which were in hospital. More to the south, at Brest-Litovsk, the railway station hospital contained 85 typhus patients; one physician had contracted the disease, likewise twelve of the members of the auxiliary service. At Kowel no figures could be obtained, but the reports received to date are in themselves quite enough to show amply that that town is a potent focus of contagion. The numerous cases were not to be found in hospitals; quite the contrary. The localities surrounding Stanislaw, as is the case for Kalusz and Halicz, are suffering greatly. Foci of contagion are being created in the commonalities, schools, and barracks. These foci are represented by soldiers or repatriated prisoners, who, in a state of absolute mental depression, weakened by hunger and privation of all kinds, lacking clothing of every description, and literally covered with lice, propagate the epidemic. Even at Budapest, 130 cases of typhus have been reported from among the convoys of repatriated people.

In Poland, the Germans finally understood the danger to which their country would be exposed by these epidemics, and the authorities got together and outlined a sanitary cordon extending from Divinsk via Orcha, as far as the Austrian frontier. This barrier no longer functions. A disinfection is carried out on prisoners, laborers, and repatriated Germans to Germany, but the necessary severity is greatly lacking. Only those who are willing to submit to disinfection undergo it. Trains coming from Russia collect along the route returning prisoners from Bielostok, Brest and Kowel, who are in an indescribable condition of filth, and these creatures are thus brought into the midst of Poland. The recrudescence of typhus at Ivangorod appears to be exclusively due to patients coming from Russia. At Kowel the same conditions have been noted. Galicia appears just now particularly menaced as typhus is fearfully rampant in Ruthenia and the Ukraine.

For the time being, the hospital authorities have prevented a diffusion of the disease by creating a barrier difficult to pass. But from the time when relations shall be reestablished after peace has been concluded the danger of epidemic extension will recur with all its gravity.

I would point out that Germany, ever on the lookout for its own welfare, has foreseen the fearful danger which it confronts, likewise all Europe, and has formed international defensive organizations at Budapest and Vienna. At the former city the French military commission, commanded by Lieut.-Col. Vix, has already created, under the direction of Dr. Courtil, an international board of health and prophylaxis whose authority will extend over all Hungary.

5. The Remote Danger of Chickenpox and Measles in Children.—LeGrand Kerr points out the importance of the adequate nourishment of children in acute infectious diseases. To this end variety is necessary, not only because there must be a continued appeal to overcome the natural aversion to food, but because, as Woods and Merrill have shown, the giving of two or more food materials at one meal puts less strain on the digestive system than the giving of an equal amount of one alone. Acute infectious disease does require a special dietary, but here two rules should be borne in mind: Due consideration should be given to the patient's previous condition and habits, and as to whether the suggested diet will agree and be acceptable; and no article of food should be forbidden without a definite reason for doing so. Restriction of the diet is often both arbitrary and unnecessary and the idea that a liberal administration of food raises the temperature in the presence of fever is erroneous. The reverse is often true; in very young children a rise in temperature will accompany acute malnutrition. It is a repeatedly demonstrated fact that the lighter articles of diet at least are as perfectly digested in the presence of hyperpyrexia as in conditions with normal temperature. Theoretically, a large proportion of protein would be indicated in the acute infections but practically their administration is impossible, so that the best that can be accomplished is to use the means of conserving the protein by giving fats and carbohydates. The fats are consistently refused, and therefore the carbohydrates seem to meet the situation. The author points out the value of the addition of sugar of milk to drinking water (one ounce of sugar to one pint of water), a fact which is not sufficiently realized. These dietetic points are of the greatest importance in relation to the real danger in chickenpox and measles, the secondary anorexia. Sometimes this follows so closely upon the infection as to suggest that habits formed through the special indulgence of the child have something to do with it. As a rule, however, it is after convalescence is well established that children exhibit a loss of appetite which persists for weeks or months. There is not only lack of desire for food, but a real distaste, which is associated with variation in growth and development. Apart from its influence on the growth of the child, this anorexia may play an important part in the production or furtherance of conditions which favor the development of tuberculosis. Treatment should therefore anticipate the occurrence of secondary anorexia and with the establishment of convalescence after chickenpox or measles, the diet should be above that which would otherwise be considered sufficient. It should be remembered that the anorexia is associated with chickenpox and measles only and not with other infections, that it is independent of the severity of the infection, that it can be distinguished from the anorexias which are the result of habit or associated with the acute features of infectious diseases, and that there is not alone an anorexia, but a real distaste for food. With exception of bronchopneumonia, this secondary anorexia is the most consistently serious complication of chickenpox and measles.

7. Sterility of Catgut.—T. Butterfield and Leo F. Ely were assigned by the Surgeon-General to make bacteriologic examination of catgut manufactured for the army during the period from December 11, 1918, to May 3, 1919. Approximately 15,000 tubes, selected at random, were examined. The number of contaminated tubes found was 1,518, or 11 per cent. As a result of this examination, they have come to the following conclusions: (1) When oil is used as an immersion fluid for the catgut, washing before planting should not be carried out if a fair check is desired on the sterility of the catgut. The suture should be taken from the tube for bacteriologic examination according to the methods commonly practised among physicians when they have occasion to use catgut. (2) Chromicized catgut is slightly more resistant to sterilization by heat than the plain catgut. (3) The infection that is found is either within or on the catgut itself and is not present in the immersion oil alone. (4) From 28 to 30 pounds pressure of live steam for three hours is absolutely necessary to sterilize catgut such as that which was submitted to the authors for examination. (5) Since any contamination may be pathogenic or otherwise, it would seem imperative that some system of federal control should be devised similar to that for biologic products so that all firms manufacturing catgut could be required to adhere to the same standards of sterility.

3. Latent Infection of Healed Wounds.—Sir Kenneth Goadby refers to previous reports made to the Medical Research Committee and published in the Lancet in July, September and November of 1916 on facts relating to "flares" after operation and their prevention by preliminary immunization; also a report made to the same committee on the bacteriology of unhealed excised and non-excised wounds admitted to home hospitals showing (1) the persistence of anaerobic organisms in such wounds, and (2) a diminution in the anaerobic flora directly attributable to the early excision of the wounds, published in the Lancet in May, 1918. The present report, also made to the Medical Research Committee, epitomises further work on post-operative flares with special reference to latent infection in healed and unhealed wounds, comprising cavities containing metal fragments, soft tissues, sequestra, etc., removed for examination during subsequent operations. In all, 226 wounds were studied; 41 which had healed and subsequently broken down, 20 healed from which tissues were removed at operations for resection or freeing of nerves, 40 closed cavities containing metal fragments, and 12 closed wounds from which bone was excised from joints, and 113 unhealed wounds from which bone fragments were removed in either the early stages of the wound or later as sequestra. A considerable number of wounds gave cultivations of

anaerobic organisms of the spore-forming variety and 44 contained *B. welchii*, 17 being healed and 27 open wounds. One hundred and forty cases showed the presence of streptococci of anaerobic type and 89 those of aerobic type; of healed wounds, 57 per cent. showed anaerobic streptococci and 29 per cent. aerobic, whereas in unhealed wounds these percentages were 67 and 50 respectively. The colon-proteus group was not often met with in wounds of from 10 to 100 days, but in those from 100 to 400 days they occurred more frequently. The author points out that in casualty clearing stations streptococci are not found in more than 20 per cent. of recent wounds. It would appear therefore that secondary infection of the wound occurs later, a fact which is not surprising and is probably entirely unpreventable. The results of his observations are briefly summarized by the author in the following conclusions: (1) That healed gas infection is an extremely common occurrence and a serious factor in the promotion of latent sepsis. (2) That anaerobic infection, though persistent in a large proportion of wounds, does not commonly give rise to secondary gas infection subsequent to operation. (3) That the chief cause of temperature reaction, breaking down of wounds at subsequent operations on both healed wounds and sinus cases, which operation was undertaken for the removal of sequestra, may be attributable to certain types of streptococci of facultative anaerobe habit, which have been demonstrated as lying present in wounds for very long periods. (4) That the use of immunization to the streptococci previous to operating on healed and semi-healed wounds, or the removal of sequestra, very greatly diminishes the risk of temperature reaction and subsequent breaking down of the tissues operated on, and he would therefore strongly recommend the routine adoption of streptococcal vaccine in the preparation of wound cases for subsequent operation, especially those involving bone section.

6. **Blackwater Fever.**—J. P. Williams has reached the following conclusions from a study of ten cases of blackwater fever in hospitals on the Gold Coast: (1) The previous history in each case tended to show that the blackwater fever of West Africa is a manifestation of recurrent and inefficiently treated malaria. This is further supported by the fact that immediate and repeated intramuscular injections of quinine, combined with galyl injected intravenously and vigorous hydrotherapy, are a satisfactory treatment. (2) The prophylaxis of blackwater fever is essentially that of malaria. (3) In galyl we have an important remedy, since it apparently has (a) a stabilizing effect upon the hemoglobin, and therefore is antihemolytic; (b) an antiparasitic action; and (c) an accelerating effect on the formation of red blood corpuscles. In one grave case in which it was successfully used the hemoglobin (Tallquist) was only 20 per cent. of the normal. Further, in no case of blackwater fever in which it has been used have any ill effects attributable to galyl appeared. (4) No person who has suffered from blackwater fever should return to an endemic area until after at least four months spent in a temperate climate. The return should be conditional upon an undertaking being given faithfully to observe the conditions necessary for the prophylaxis of malaria, *e.g.*, the taking of quinine as a prophylactic according to a recognized system and the proper use of a mosquito net. Otherwise there is grave liability to a second attack, which would probably prove fatal. Moreover, people who hold, as the author's patients did, that it is not necessary to take quinine systematically in West Africa, are, by spreading their pernicious doctrine, a danger to other Europeans.

4. **The Diagnosis of Myocardial Debility.**—R. T. Thorne thinks that no practitioner of experience can fail to have been struck by the not infrequent occurrence of cases displaying evidence of cardiac debility, yet showing no sign of dilatation or valvular murmur on examination. There is probably no physician who has not met numerous cases complaining of shortness of breath, cold and congested extremities, palpitation, and perhaps pain in the cardiac region, and yet the most careful examination fails to reveal any evidence of organic disease. The question therefore naturally arises: Are there no means of ascertaining the condition of the myocardium? Or again, what practitioner of experience has not met the tragedy of sudden death after apparent recovery from pneumonia or diphtheria, perhaps more often in one who appeared, on previous examination, to be in perfect health? Cannot such a calamity be foreseen and prevented? Is there no method by which we can accurately estimate the strength of the myocardium? Is there no instrument which will enable us to detect a weak and inefficient heart? Dr. Thorne believes that the differential stethoscope will supply our need. When we remember that the heart is nothing more than a muscular pump, divided into four compartments and provided with four valvular openings; that in the muscle alone resides the power which carries on the circulation; and that the valves themselves are only of minor importance, we can realize the immense value of being able to ascertain the muscular efficiency of an organ on which life depends, and which is nothing more than a muscular syringe. The latest textbooks tell with regard to the symptoms and signs of myocardial changes or debility that they are uncertain and vague, and we learn practically nothing from them as to diagnosis. In fact, our greatest physicians have had to admit in the past that no exact method was known of ascertaining the condition of the heart muscle. We see a man with pronounced valvular disease continuing his work for years in good health, provided there is adequate compensation. On the other hand, we see cases with no valvular disease suffering from evidence of cardiac debility. What is the explanation? The former has a healthy heart muscle, the latter has not. The differential stethoscope enables us to diagnose the latter condition. The differential stethoscope consists of the usual binaural ear pieces and tubing, which are connected with a hollow aluminum chamber, divided transversely by a septum into two compartments, the upper being connected to the ear pieces by the tubing, the lower having the chest piece attached to it. The center of the dividing septum is pierced by a conical opening, into which a metal cone can be inserted or withdrawn, closing it completely or varying the size of the opening, and thus allowing more or less of the sounds to reach the examiner's ear. The position of the cone is indicated by a pointer on the upper surface of the chamber, and the figures shown there give the values of the sounds passing through the aperture with the cone in varying positions. Now it has been found by experience that the value of the first sound at the apex in a normal healthy heart is about double that of the second sound at the base. For example, in a healthy heart, if the first sound at the apex registers 3.2, the second sound at base will be in the region of 1.6; or if the former is 4.7, the latter will be about 2.4. Thorne calls this the normal 100 per cent. ratio. A ratio falling below 50 per cent. normal standard is, in his opinion, evidence of myocardial debility. To use the differential stethoscope, apply the chest piece to the apex of the heart, having previously rotated the pointer one complete revolution from left to right from the closed position, so that it stands at 0. Now slowly close it, turning the pointer from right to left until the first sound is just not audible, mark the figure on the dial, perhaps it is 3.2. Now place the chest piece over the aortic base, and repeat the same procedure, noting the figure at which the second sound is just not audible, say it is 2.4. Now we have the figures 3.2 and 2.4 giving us a ratio of about 25 per cent. normal; this would indicate a weakness of the myocardium. A normal heart would prob-

ably have given a reading of 3.2, 1.6, 4.7, 2.4, or 6, 3.2. That is about 100 per cent. normal standard. While working at a military hospital Thorne has found the differential stethoscope of great value in detecting malingerers who plead heart weakness, palpitation, and breathlessness, when they do not wish to return to duty. His experience leads him to believe that it can be relied on in the diagnosis of such cases. According to the author, if his facts are accurate, the value of the differential stethoscope can hardly be exaggerated.

5. The Effects of Moderate Exercise on the Blood Pressures.—Gerald Smythe in seeking material for his paper could conceive of no better example of "moderate muscular exercise" than that of the physical training practised as a routine in the army. The British Army Physical Training Manual gives most clearly and concisely the scope of the training soldiers undergo and describes how exercises should be given for the development of every organ of the body, including the brain, which is taught to control the muscles and make them respond readily to any message it should give them. Smythe is of the opinion that an hour of such training can be reckoned as a good standard of moderate exercise, and it was before and after such that he took his blood pressure readings. A summary of the figures derived from Smythe's investigations as to blood pressures by the auditory method, on 100 officer cadets, whose ages varied between eighteen and thirty-nine years and who were all fit men of good physical development and practising moderate muscular exertion, is as follows: 1. The pulse rate tends to be only slightly altered. 2. The systolic blood pressure is lowered by 5 mms. 3. The diastolic blood pressure remains the same. 4. The pulse pressure was lowered 5 mms. All observers seem to be agreed that during the actual performance of an exercise involving physical strain the systolic blood pressure rises, and that when the effort is over there is a fall in the pressure. Smythe's opinion is that during exercise the ventricular contraction is more vigorous, and at first, at any rate, there is no alteration in the peripheral resistance, so that the blood pressure is raised. During the process of exercise the muscles may produce a substance, the result of muscular metabolism, which causes vasodilatation and so lowers the peripheral resistance. Oliver has suggested the formation of lactic acid or some other substance which destroys the adrenalin which maintains the normal muscular tone of the arteries. This is all speculation and there is no proof that any of the above theories is correct. But this we do know, that it is undoubtedly the dilatation of the arteries and capillaries in the muscle bed which causes the fall in blood pressure rather than the weakness of the ventricular force. In Smythe's observations in most cases the heart beat was scarcely altered after exercise. These are the summary of results: 1. The auditory method is the best way of determining the blood pressure for ordinary purposes. 2. The average systolic blood pressure in a resting man between the ages of eighteen and thirty-nine is 125 mms. 3. The average diastolic pressure is 86 mms., and is unaltered after exercise. 4. In the majority of cases the systolic blood pressure is lowered after moderate exercise. The lowering is caused mainly by the dilatation of the arteries and capillaries, and not by fatigue of the heart muscle. 5. The average pulse rate in the series was 78 per minute, both before and after exercise. 6. The effects of moderate exercise on the system are beneficial, inasmuch as the peripheral dilatation caused thereby increases the warmth of the skin, and provokes the flow of sweat from the sweat glands, without taxing the heart to any degree. After physical training on Swedish lines the man finishes up unexhausted and fresh.

Berliner klinische Wochenschrift.

March 17, 1919.

The Genesis of Cicatricial Cheloid from Modern Conceptions.—Menes states that cheloids result from irritations occurring during cicatrization, such as infectious or external causes which naturally predominate in exposed parts, such as the head. As to predisposition, a place should be given to scrofulosis, tuberculosis, and syphilis which interfere with the process of tissue repair. Recurrences occur when prolongations of cheloid tissue invade the surrounding structures and thus the cheloid resembles carcinoma; on account of its histological make-up, which is similar to sarcoma, while from excessive proliferation at the very onset cheloid is to be distinguished from benign fibroma.

Varicose Veins in the Etiology of Sciatica.—W. Alexander studies the literature of this much mooted question. The oft contradictory data obtained from pathological examination being insufficient, one must solve the question by clinical facts. Now, practice contradicts on every point the doctrine that varicose veins may give rise to true sciatica. Therefore, venous ectasis should be eliminated from the etiology of sciatica and placed in the chapter of differential diagnosis. The writer concludes by giving a synoptic table of the elements of this differentiation, all of which are perfectly well known.

Münchener medizinische Wochenschrift.

March 14, 1919.

Nonspecific Protoplasmic Activation.—W. Weichardt and E. Schrader have carried out a quantitative study of this property of the organism to react by means of an increase in the processes of defense against all kinds of substances administered by parenteral routes. The first series of injections were made in rabbits having in the first place received antityphoid vaccination. Under the influence of injections of deuteroalbumose, nucleate of soda, and peptone, a sudden rise in the strength of the antityphoid agglutinins took place. The injections were also given to unvaccinated animals and in them an increase of the agglutinins was produced, although less marked. In this latter series of injections the action of the deuteroalbumoses was not so evident as in the vaccinated animals. From the viewpoint of dosage, the writers were able to note that an increase of the amount of the products injected resulted in a greater activation of the process of defense, but that the general behavior of the tracings nevertheless remained the same for each substance injected. From their experiments, the writers conclude that nonspecific parenteral therapeutics are perfectly justifiable. Treatment with milk injections is included and, in point of fact, give very happy results in the most varied forms of infectious diseases.

The Diagnosis of Aneurysm of the Abdominal Aorta, Particularly Radiodiagnosis.—A. Boettner points out that the diagnosis should include the subjective signs (gastric crises, gastroxynsis, various abdominal pains, etc.); phenomena of compression of the pancreas, ureters, splenic, or renal vessels. When the aneurysm is seated at the level of the mesenteric arteries it gives rise to symptoms of intestinal arteriosclerosis. Paraplegia due to involvement of the vertebræ and medullary compression has even been met with, likewise edemas from compression of the vena cava, etc. Radiodiagnosis, which has been most uncertain until recently, was successfully carried out in two instances by the writer, by taking the following precautions: thorough emptying of the intestine, gastric, and intestinal insufflation, and finally pneumoperitoneum. A pulsatile tumor could then be seen, which was pathognomonic.

Deutsche medizinische Wochenschrift.

March 13, 1919.

The Value of Food in Sufficient Quantity to Satisfy.—O. Kestner remarks, and rightly so, that the estimate of foodstuffs in calories is decidedly insufficient. It is an arbitrary criterion which does not take into account physiological facts, such as the appetite, digestibility, etc., nor of clinical experience which can do without the question of calories but not of the nitrogen content. The writer studies the factors which instinctively guide man in his daily feeding. Hunger is partially produced by "the activity of emptiness" of the digestive organs, this being the result of the absence of the acid gastric secretion. On the contrary, satiety is related to the gastric motor activity and secretion as well as to the blood changes which depend upon it. Now, it is the duration of the contact between the food and stomach which constitutes the satisfying value of a given food;

this duration varies according to the food. The duration of the progress through the intestine of the food is, for that matter, to a certain extent proportional to the gastric time of digestion. Looked at from this viewpoint, foodstuffs possess a much different value from that of their calorimetric value. Meat possesses a value of the higher order on account of the excitor-secretory action of its extract: 200 grams roasted meat provokes secretion of 1246 c.c. and a contact of four hours; 200 grams of toasted bread provokes secretion of 839 c.c. and a contact of two and one-half hours. Generally speaking, vegetable foods have a less satisfying value than meats and a vegetable diet necessitates more frequent meals. It therefore is more applicable to rural professions than to city people who can only partake of two or three repasts a day on account of working hours. Sugars are absorbed slowly and have a slowing action on the passage of food through the intestine, therefore a prolonged satisfying action, so that they should be taken at the end of meals. Various simple or complex dishes are examined by the writer from this essentially practical and really physiological viewpoint.

Gazette des Hôpitaux.

March 22, 1919.

Cocaine Intoxication.—Giroux, who has been associated with Courtois-Suffit, the authority on forensic medicine and hygiene, writes on this subject. The use of the drug is on the increase in Paris and the author is interested in this study in the sniffers only. In the occasional user the effect on the sniffer is not unlike that of alcohol. The subject is filled with energy and must act or talk. The experience is shortlived, seldom lasting over half an hour, and is followed by the most burdensome feeling of lassitude, combined with restlessness. As he walks restlessly about his legs seem to buckle beneath him, and if he lies down he suffers from tachycardia, accompanied by precordial anxiety. He is in a state of acute cocaine poisoning and exhibits pallor, fixity of the eyes, dilated pupils, etc. This state may disappear quickly or only after several hours. To obtain these symptoms the subject must be unaccustomed to the drug or the dose must be large, for the condition described is an intoxication. In a sufficiently small dose the period of exaltation is less strenuous and the reaction limited to depression. In the habitué the first sniff is always disagreeable after the initial euphoria, but the need of a stimulant drives one to take a second, and, unless the sensations which suggest the drug are removed, the subject is bound to become an addict. The latter has his periods of physical excitation following each sniff. Mental workers can concentrate and work rapidly, and do work of an unsuspected excellence. Sociable men talk easily and brilliantly. Men of action are capable of unlimited effort and are tireless. This period of exaltation, however, as in alcoholism, often shows a moral bias. The egotism of the fiend is notable and he cannot bear contradiction, while he is rendered furious by trifles. He does not sleep and suffers from anorexia. In many ways he is like a hypomaniac, and may even exhibit violence toward people or inanimate objects. When his condition is confirmed he has troubles of the special senses which greatly facilitate the development of hallucinations. The phenomena of chronic cocainism are sufficiently well known, but diagnosis may present difficulties. It is not always easy to determine whether the cocainism is acute or chronic. In the masked case marked irritability, cerebral excitation with a fantastic humor, diarrhea, insomnia, loss of appetite, etc., may cause a suspicion of the habit. Cocainism must be distinguished from morphinism and mixed addiction.

Revue médicale de la Suisse romande.

March 19, 1919.

Subalimentation and Edema of Famine.—Guillermin and Guyot state that inanition is something which all medical men have a chance to see in ordinary practice, as in psychoses and cancer of the esophagus. But never up to 1915 had physicians now in practice expected to witness a veritable plague of famine in Europe. This attitude was a natural result of the ever-increasing improvement in transportation; but this optimism had to yield to the effects of war on all of the components—production, conservation, transportation, and distribution. At present few statistics are available. In Cologne, believed to have been fairly well fed, the child mortality, which held its own for years, rose considerably in 1918, reaching over 18 per 100 births. These figures evidently refer to nurslings, as the increase is attributed to inferiority of breast milk. In Keil the amount of scrofula in the school children has doubled during the war. The death rate in Prussia in subjects over 60 has increased nearly 50 per cent. In Koenigsberg the deaths from tuberculosis have doubled. The medicinal doses for the ailing have to be cut down to avoid intoxication—mercury for example in syphilis. Amenorrhea, abortion, post-partum hemorrhage, and still births have increased while gout, obesity and eclampsia have diminished. The specific disease of subalimentation, however, is edema. It has now become well known and even the Swiss physicians see it in French prisoners. Conditions which call for increased consumption of food aggravate it, as cold and severe manual labor. The loss of weight may attain 40 per cent. and the contrast between emaciation and edema is striking. In Germany the condition was first noted in the Russian prisoners and the underfed Poles. Next to emaciation and edema the anemia is conspicuous. Edema may be present anywhere and the distribution resembles that seen in nephritis. The latter, however, is not seen. Hemeralopia is, of course, common. These edema subjects fall an easy prey to epidemics. Scurvy appears more as a complication than part of the disease. This is in contrast to the starving at the siege of Paris in 1871 when edema was merely a forerunner of scorbutus.

Correspondenz-Blatt für Schweizer Aerzte.

March 15, 1919.

Studies in Epilepsy.—Tramer speaks of the apparent absence of all types seen in analysis of many cases of epilepsy. Paroxysms of this affection are seen in any and all psychic or psychopathologic states when the latter are chronic. We may, therefore, speak of cases with and without dementia, with and without affects, etc. The psyche may or may not be normal. In regard to secondary dementia it is often difficult to draw a sharp line between physiological variation and disease. In other words, the mere fact of being an epileptic should in itself affect unfavorably the subject and cause unusual behavior in the soundest mind, while on the other hand the so-called epileptic alteration is seen in nonepileptics. A supposed pathological psyche may after rigorous study be found to be within normal bounds. The author holds a brief for the existence of an acute type of the disease which, while it may persist for a long while, will end spontaneuosly in recovery. In some of these the so-called secondary dementia is plainly in evidence, yet when the attacks cease the patient recovers from this as well. This fact teaches plainly that secondary dementia of authors may be only functional. Of neither the exogenous or endogenous causal factors of the disease do we know much. The epileptic with infrequent attacks—they can be rendered still less frequent with a little bromide off and on—is at times a man of unusual mental power. Another special type is epilepsy with primary mental defect, and this is only too common. In such cases the seizures form the only component to be reached by treatment and bromides and salt starvation may hold back the secondary dementia. The marginal gliosis peculiar to epileptic brains must be looked on as a substitution tissue which replaces the loss in nervous elements.

The Pandemic in Macedonia in the Spring of 1918.—That other territories were attacked as early as Spain appears to be shown by an account of the disease in the French Macedonian army in May-June of that year. This outbreak was at first confused with pappataci fever, but was soon identified with influenza when pulmonary complications set in. It is now fairly certain that the same affection appeared in Spain, Italy, and Macedonia at about the same time, but that for some unknown reason Spain became the chief distributing point.—*Office International d'Hygiene Publique.*

AMERICAN MEDICAL ASSOCIATION.

Seventieth Annual Session, Held in Atlantic City, June 9, 10, 11, 12, and 13, 1919.

(Special Report to the MEDICAL RECORD.)

SECTION ON DISEASES OF CHILDREN.

First Day—Wednesday, June 11.

DR. FRANKLIN P. GENGENBACH OF DENVER IN THE CHAIR.

Chairman's Address: Our Section in War Work.—Dr. FRANKLIN P. GENGENBACH of Denver made this address. He said that it was fitting that there should be some permanent record of the work done during the war by the members of the Section on Diseases of Children. He had therefore made a survey which included work done in the service of the army and navy, Red Cross work abroad, work in teaching, child welfare work at home, and work in connection with the selective draft and Red Cross work at home. The list of those who had rendered such service was read and placed on permanent record. It showed that 120 pediatrists were registered in this service. Dr. Gengenbach told how the pediatrician had adjusted himself to the care of adults, not a difficult matter since he was first trained in general medicine before he became a pediatrician. He also laid emphasis on the importance of the child welfare work that lay ahead of them.

The "Victory" of Children's Year.—Dr. ANNA E. RUDE of Washington presented this communication in which she reviewed the work of children's year undertaken by the Children's Bureau and the United States Public Health Service. The report dealt with the protection of mother and child, the home care of the child, the care of the child during the school age, recreation, and the child needing medical care. She told of the assistance that they had had in their work from the Women's Council on National Defense with a membership of 11,000,000 women. Statistics were given showing the results of the weighing and measuring in a number of States, and it was shown that the results of the work of children's year were already visible in the many permanent activities that had been established following this campaign. At the International Conference on Child Welfare recently held in Washington minimum standards of child welfare work had been submitted. These were later presented and discussed at the regional conferences which were held in different cities throughout the country. At the general session of the Washington conference the economic and social aspects of child welfare were discussed. The details of these standards were presented. They included age minimum, educational minimum, physical minimum, hours of employment, etc., for children; minimum standards were presented for the protection of mothers and children, of infants and children during the preschool age, of school children and adolescents; standards for children needing special care with reference to home care, adequate incomes, removal of children from their homes, principles governng child placing, the care of children of illegitimate birth, rural social work, recreation, juvenile court, the mental hygiene of defective children, and child welfare legislation.

Sir ARTHUR NEWSHOLME of England stated that what he had seen at the regional conferences confirmed what Dr. Rude had said, though she had given but a bare outline of what he had observed in reference to the result of this work. The great value of the work was not expressed by the actual weighings and measurements. Even inaccurate weights and measurements had some value in that they drew the attention of the mothers to the importance of keeping their children in good physical condition. He emphasized the importance of having a physican available in connection with child welfare work and of having him consulted at frequent intervals. He had on a former occasion made a rather exaggerated statement, saying that doctors, as a rule, did not know a well baby when they saw it. That was not really true, but it was true that it was only exceptionally that a doctor had the opportunity of seeing well babies. If they saw healthy babies more often they could better detect the early signs of disease. In England one-third of all infants were periodically examined and nothing short of medical supervision would suffice. It might for some time be necessary to have baby weighings without doctors, but we must work toward medical supervision. The help of the medical profession was needed in this work because it deserved their very best support.

The Pediatrician at Home During the War.—Dr. FRANK C. NEFF of Kansas City, Mo., presented this paper, in which he said that practically all pediatricians had offered their services to the Government, Red Cross, draft board, or other war agencies. Many who volunteered for army work were not called. Teaching hospital, dispensary, and child welfare work were maintained by them. Their work was increased because of the responsibilities brought about by the shortage of physicians and the great amount of sickness. Pediatricians had taken an active interest in the care of the children of men who were in the service. The war had shown the value of child conservation and had shown the need of child welfare work in rural districts as well as in cities. The pediatrician stood ready to do his part in a program offered by the lessons of the war, namely, the betterment of child life, so that it might grow to the strongest physical, mental, and moral manhood.

Dr. J. M. DODSON of Chicago emphasized the point that Dr. Newsholme had made, that the physician rarely saw the well baby, normal baby, and thought that every school teaching pediatrics should have a postnatal clinic or a child welfare station in connection with it. If there was to be a choice as to whether the student should see normal or sick babies, it was better that he should see normal babies. If the student knew the normal baby and how to care for it, the sick baby would be reasonably safe in his hands. He also called attention to a fallacy in the argument that all defects found in the draft examinations were due to errors in the early care of children. Many were rejected for defects of vision that could not be blamed on early care. Defects of vision were responsible for 11 per cent. of the rejections. Diseases of the circulatory apparatus were responsible for 13 per cent. of the rejections, and it was extremely rare that physical culture would have prevented these diseases. There were 11 per cent. of rejections because of hernia, and certainly physical culture would not prevent hernia.

Dr. PERCIVAL J. EATON of Pittsburgh called attention to the deterioration in the milk supply during and since the war. It had thus far shown no tendency to come up to prewar standards. The bacterial count ranged from 2,500 up to 100,000, and even up to 259,000. Letters written to the secretaries of milk companies in different parts of the country had shown the same thing. The pedatrician should take up this matter and try to restore the quality of the milk as we had it before the war.

Dr. S. MCC. HAMILL of Philadelphia asked if in the decision upon these standards pediatricians had been consulted. He asked this because child welfare was a community problem involving all other sanitary problems and social and economic problems.

Dr. F. V. DAVIS of Chicago made a plea for closer cooperation between the obstetrician and the pediatrician. She expressed the opinion that there should be a pediatric clinic in connection with every maternity hospital, and the student could also study the normal baby in the maternity wards.

Dr. H. F. HELMHOLZ of Chicago brought out the point that the man who took care of the sick child was not necessarily prepared to do preventive work, because in order to do effective preventive work an entirely different mental attitude was necessary. It took six months to teach a nurse the proper attitude in reference to preventive work. The fact should be emphasized that preventive work was different from the practice of medicine, and that it took special training in order to be able to do such work as it should be done.

Dr. RUDE, in closing, replied to Dr. Hamill's question by giving the names of pediatricians who had assisted them in arriving at these minimum standards.

Dr. NEFF emphasized the need of medical supervision in child welfare work and recommended the plan

adopted in Massachusetts. The work should be done through the cooperation of medical and social service agencies, but should be kept free from politics.

The Work of the Children's Bureau of the American Red Cross in Lyons.—Dr. CLIFFORD G. GRULEE of Chicago made this presentation, which was illustrated by lantern slides.

Dr. FRANK LAMB of Cincinnati, who had worked with Dr. Grulee, spoke of the condition met with in France. He said there was comparatively little malnutrition. After they had organized to take care of contagious diseases they had very few of them. There was very little congenital syphilis. Nearly every child when it came under ther care had fleas, 75 per cent. had lice, and many had scabies and impetigo. The latter sometimes occurred in a very severe form; he had seen four cases in new-born babies where it led to the development of meningitis. He had never seen that in this country.

The Artificial Feeding of Athreptic Infants.—Dr. W. MCKIM MARRIOTT of St. Louis presented this communication, in which he used the term "athreptic" in reference to the well-known condition of extreme malnutrition of infants known as marasmus, or infantile atrophy. The condition of athrepsia was a condition of virtual starvation in which the volume flow of the blood was diminished. This diminished flow of the blood was dependent, in part at least, upon a decreased blood volume, seemingly the result of a decreased protein content of the plasma, and consequent inability of the blood to maintain its water content. Very considerable amounts of food were indicated to meet this condition, yet the tolerance of many of these children for food was low, and digestion and absorption were necessarily poor. The tolerance of the infant for food might be increased by the use of gum acacia saline mixture intravenously, as the writer showed in the Proceedings of the American Pediatric Society for 1919. The problem still remained of providing a food containing the elements essential to nutrition, and which could be fed in large amounts without causing gastrointestinal disturbances. In cases in which breast milk was not available, the use of lactic acid milk could be taken in larger amounts than sweet mlk. They had come to regard buttermilk and protein milk as their chief reliance in the feeding of infants with gastrointestinal disturbances. Fat free lactic acid milk, however, was low in caloric value. The carolic value might be increased by the addition of sugar and starch, but even when enriched by sugar addition it was not particularly adapted to the feeding of athreptic infants, particularly those under three months of age. There was no reason *à priori* why the fat should all be removed from lactic acid milk. In order to furnish the additional carbohydrates required by these athreptic infants they had employed the dextrines and glucose, the latter being absorbed with great rapidity. Glucose was very readily fermentable and hence had not been used extensively in infant feeding. The dextrines, on the other hand, were not readily fermentable. It therefore seemed that commercial glucose, otherwise known as corn syrup, being a mixture of dextrin, glucose, and maltose, might be suitable for the purpose. They had added carbohydrate in the form of corn syrup to the whole lactic acid milk and used it in feeding athreptic infants, and the results were as would have been anticipated. There was no tendency to diarrhea, even when as much as 10 per cent. of the carbohydrate was added. There seemed to be almost no limit to the amount of carbohydrate that could be added to such a milk mixture. In addition a 5 per cent. solution of corn syrup might be given between feedings, almost *ad libitum*, as a means of supplying further calories The thick syrup was rather inconvenient to handle and could best be used in a solution containing 50 per cent. carbohydrate. As such a mixture was thick a nipple with a large hole must be used in feeding. Up to the present time the writer had fed forty infants, varying in age from one and one-half months to 18 months, from periods of four days to eight weeks. The amount of carbohydrate added varied from 10 to 15 per cent. A gain in weight was noted in these children when a sufficient caloric intake was reached, and generally continued steadily for days and weeks, interrupted only by acute infections. Few infants whose weight was as low as 50 per cent. of the normal weight for the age gained on less than 160 calories per kilo, and many required 200 calories or more. The gain in weight in these infants was not due to a process of "water logging." There was no tendency to edema and none of the excessive flabbiness observed in condensed milk babies. It might be noted that, although the food described contained a high percentage of carbohydrates it was also high in protein and fat, the relative proportions being not unlike those of ordinary milk mixtures. Ths mixture as described contained from 25 to 30 calories per ounce. In concluding, Dr. Marriott emphasized the fact that he did not consider this type of feeding as a panacea for infants. It was simply a type of food that enabled one to administer a considerable amount of nourishment in an easily assimilable form.

Dr. FRITZ B. TALBOT of Boston said this paper gave a great deal of food for thought. One point brought out was that the underweight child required more calories than the normal child of the same age. That had been brought out in their experimental work on basal metabolism. That was a point overlooked in the past because of the teaching they had had. There was one point not brought out, and that was that a large number of these athreptic infants had a subnormal temperature and if the temperature could be restored to normal they would begin to gain. These children were very tolerant of sugar, but they had to be watched closely, for when the sugar went above a certain percentage they might get diarrhea. Perhaps with the type of sugar that Dr. Marriott had used this was not so likely to occur.

Dr. ALFRED F. HESS related his experience with twelve infants fed on this form of sugar. These babies did exceedingly well on corn sugar. Corn syrup was cheaper than cane sugar, and if it were shown that it was absorbed better it would be of great value.

Dr. J. P. CROZER GRIFFITH of Philadelphia said he had asked the chief resident physician of the Children's Hospital in Philadelphia if he were compelled to choose one kind of diet for an infant what it would be, and he said buttermilk; that was the common buttermilk mixtures. He was glad to hear Dr. Marriott's paper, which corroborated his own experience as to the ability of the child to take a large amount of sugar. He had had little fear of high percentages of sugar. It was often difficult to have the parents prepare the buttermilk because it required some judgment, and for this reason he had tried to get away from buttermilk by making a milk of the same percentage composition, but it did not work as well as the buttermilk, and this was probably due to the presence of the lactic acd in the buttermilk. They had been told by Finkelstein that fat would be tolerated by these children if the protein and whey were reduced in quantity, and that was his idea.

Dr. CHARLES GILMORE KERLEY of New York said that Dr. Marriott's paper had impressed him very favorably indeed. He had used a great deal of lactic acid milk, having used largely the fat free product or a very weak percentage of fat in intestinal disorders, and when the intestinal disorders cleared up other food was substituted. He would not have had the courage to have used sugar in the large quantities that were mentioned in the paper. He would be interested in giving it a trial, as carbohydrate was a necessity in these very marked cases of malnutrition in little babies. He had been giving carbohydrates in these cases in the form of starch and barley water. His procedure had been to use unsweetened evaporated or condensed milk cooked with starch and then the sugar added afterward, and that had given him the best results.

Dr. I. H. KERLEY of New York said that in these marantic cases there were many difficulties caused by casein of cow's milk forming hard curds, while that of mother's milk made a flocculent curd. He had had great success with evaporated milk which was heated and the protein molecule broken up so that it did not form a hard curd. One ounce of evaporated milk contained two and one-half calories, so that the caloric value might be increased by the use of evaporated milk, and then maltose or glucose added. Two per cent. lactic acid milk had given wonderful results in diarrheal diseases in children and its use was specially indicated in such conditions. In marasmus protein milk finely divided gave good results.

Dr. HENRY F. HELMHOLZ of Chicago related his ex-

perience with commercial corn syrup. They had used it in 125 babies in their milk station with very good success. They had used it as they would use a sugar and flour mixture. However, when the summer was over the nurses said that if they were going to keep on using the syrup they would leave, because of the difficulty of handling the syrup. He asked Dr. Marriott if he had found a way of handling the syrup conveniently. If it could be more easily handled, corn syrup made a cheap and excellent addition to the foods that were suitable for infants.

Dr. Lewis Hill of Boston said that he had felt for some time that one of the most important things in infant feeding was the proper understanding of the use of carbohydrates, particularly sugar. He was glad to hear what Dr. Kerley said, for he had done the same thing and wondered if he was right or wrong. Some years ago he and Dr. Talbot increased gradually the amounts of carbohydrates and kept the other elements of the food the same, and they found that the high carbohydrate content increased the nitrogen and salt retention. He believed this was because the carbohydrate acted as a nitrogen sparer. He had fed rather low protein, just enough to cover the nitrogen needs of the body, and had supplied the necessary number of calories by a mixture of maltose and dextrose. He found that babies could take 10, 12, or 14 per cent. of carbohydrate, and that the gain in weight under such feeding was not due to water retention. He believed there was a tpe of infant with an alkaline intestine that needed a great deal of carbohydrate. Such babies were likely to be constipated and were helped by being kept on a high percentage of carbohydrate until they gained weight or had diarrhea.

Dr. T. C. McCleave of Oakland, Cal., said he had been pondering for some years as to how to give more carbohydrates to certain types of children, and in some instances this had been explained by the method of feeding Dr. Marriott had described. He would like to ask about the intervals between feedings. He suggested that possibly the secret of being able to give a larger amount of fat was dependent upon the particular combination of carbohydrates furnished in the corn syrup. The glucose was immediately absorbed and the maltose in a little longer period. The proper absorption of the protein and fat was dependent upon a proper amount of carbohydrate. It seemed to him the beneficial effect of this method of feeding carbohydrates might be explained by this particular combination of sugars, together with the milk sugar that was normally present in the milk.

Dr. Marriott, in closing, referred to the point raised about the subnormal temperature, and said this opened up a very interesting question. In speaking of the pathogenesis, he had referred to the diminished volume of blood and the fact that the flow of blood was diminished. As the volume of blood was increased the subnormal temperature tended to disappear and the child began to gain. He thought the subnormal temperature was dependent on the diminished volume flow and that when the volume flow was increased the temperature was raised and the child began to gain. As to the method of preparation they boiled the milk, cooled it, inoculated it and put it in a thermos bottle over night. They made the corn syrup up in 50 per cent. solution and then this thin solution could be mixed easily. The feeding intervals were four hours, six feedings in twenty-four hours, that gave 280 calories per kilo body weight, so it was not necessary to feed more frequently. As to the effect of the carbohydrates on the fat, the carbohydrate influences fat absorption in two ways in the intestinal tract. A certain amount of carbohydrate was required for the absorption of the calcium salts and it was an advantage in intestinal metabolism. They had found no trouble with acetone bodies from the feeding of these high percentages of carbohydrates in the form of corn syrup. While the high percentage of carbohydrate was being fed the stools of these children were watched very carefully, and if there was a loose stool the corn syrup was stopped at once.

The Deleterious Effect of Alkalinization of Infants' Food.—Dr. Alfred F. Hess of New York read this paper, in which he made the statement that in the preparation of infants' food no regard was paid to its reaction, and such substances as sodium bicarbonate were added without thought in this regard. The same was true as regards proprietary foods. Most of them were of alkaline reaction, some of them in a high degree. The writer found that the antiscorbutic vitamine was peculiarly sensitive to an alkaline reaction and rapidly deteriorated in milk that had been rendered alkaline. He attributed the frequent occurrence of infantile scurvy in infants fed on malt soup preparations to the potassium carbonate which it contained. Experiments on animals seemed to confirm his conclusions. He suggested that potassium citrate be used by the manufacturers of proprietary foods instead of the alkaline potassium carbonate. He also suggested that this question of reaction might play an important role as regards other vitamines and that it might not be innocuous that cod liver oil was rendered alkaline in the preparation of the emulsions commonly employed.

Dr. Harry Lowenberg of Philadelphia expressed the opinion that while this work of Dr. Hess's was very interesting and enlightening it seemed hardly fair to draw such sweeping conclusions from one case and four guinea pigs, convincing as the data seemed to be in the light of clinical experience. He had yet to see scurvy develop in a case fed on alkalinized food. He had fed many infants on malt soup extract and potassium citrate and he never fed orange juice, so it was difficult to allow his convictions to be swept away by a report of this kind. He would like to see the work carried on still further.

Dr. Julius Hess of Chicago called attention to the fact that when Keller gave the formula for the use of malt soup he distinctly warned against their use for long periods on account of the possibility of their producing scurvy. In prescribing a food of this kind it should be understood that it is not to be given indefinitely without the supervision of a physician.

Dr. Charles G. Kerley of New York stated that one of the criticisms against the paper was that it was too conclusive and it proved the point too definitely. They did not have difficult feeding problems settled quite so readily. They had been feeding alkaline foods for years and yet they saw very little scurvy. He felt that the case against the alkalinization of food so far as its interference with the vitamine content had yet considerable to be said about it. As to the use of malt soup producing scurvy or having a tendency to produce scurvy over other means of feeding, Dr. Hess was right. He would not think of feeding an infant on a malt soup mixture without the use of orange juice at the same time because it certainly had a tendency to produce scurvy more than any other type of feeding he had encountered. He felt that if alkalinization of the food was a factor in the production of scurvy they would see more scurvy than they did.

Dr. J. P. C. Griffith of Philadelphia referred to a report of the American Pediatric Society presented some years ago in which they found that certain proprietary foods produced scurvy, and at that time the claim was made that it was not the proprietary foods but the boiled milk with which they were prepared that were responsible for the scurvy. It was true that the feeding of proprietary foods might be followed by scurvy, but perhaps simply because the scurvy followed the feeding the conclusion should not be drawn that the scurvy was due to that particular food. He had seen ten breast-fed babies develop scurvy, yet he would not like to say that the breast milk produced the scurvy. He felt that they did not have sufficient knowledge on this point as yet to state that the alkalinization of food was responsible for scurvy, for if that were true they would be seeing scurvy all the time.

Dr. St. Geo. T. Truman of Richmond, Va., said that during the last two years he had been looking for scurvy and had seen more than during the ten years before, and he felt that these cases came from the use of certain proprietary foods.

Dr. J. I. Grover of Boston said he felt rather sure that scurvy was not rare. They saw a case every two, three, or four days. He felt that the boiled and dried foods were responsible for the condition.

Dr. Lewis Hill of Boston said it was sometimes necessary to use certain proprietary foods in order to get a proper amount of carbohydrate, and he felt that

it was safe to use them if a proper amount of orange juice were given.

Dr. E. V. Davis of Chicago said she also protested against the condemnation of malt soup because it was prepared and sold as a proprietary food. She had seen healthy babies produced on such a preparation and they did not have scurvy if they were not fed on such a food too long. If she employed a food of that kind she added vegetable soup, orange juice, or carrot when the child was seven or eight months old. She stated that they had been putting soda into their beans, for they fed bean soup, but her attention was called to the fact that the soda was said to kill the vitamines and she had stopped adding it to the beans and indeed had stopped the use of alkalies to a certain extent, but she still thought the question as to the effect of alkalies in the food was unsettled.

Dr. E. C. Fleischner of San Francisco said he thought they were losing track of the subject which they were discussing; they were not discussing the etiology of scurvy. No one doubted that a certain amount of raw cow's milk kept a child free from scurvy. He brought out the point that a highly alkaline food could be given if large amounts of milk were used with it for there would then still be enough vitamine present to prevent the development of scurvy.

Dr. Frank C. Neff of Kansas City said it was brought out in the course of the discussion that dextromaltose was useful for the relief of constipation. In his experience when potassium carbonate was added there was no such relief.

Dr. Alfred F. Hess, in closing, said Dr. Kerley had answered the question with reference to malt soup as a factor in the production of scurvy. He could not explain it but if 100 children were fed on malt soup, they would get almost 100 cases of scurvy; he did not mean active cases with bulging red gums, subperiosteal hemorrhage, etc., but the mild cases with pallor, petechial spots, and tenderness of the femur. He thought there was a little misunderstanding in regard to malt soup. Malt soup contained 1.1 per cent. potassium carbonate, which was a larger amount of alkali than was present in some of the other foods. The statement had been made that he had insufficient basis for his conclusions. He could have duplicated the case and the experiments with the guinea-pigs many times over. He knew of no particular in which an animal scurvy differed from human scurvy and an antiscorbutic for guinea-pigs was an antiscorbutic for human beings, so that we could accept animal scurvy in the interpretation of human scurvy. Someone brought up the point of dried foods as a cause of scurvy. He did not think the drying was a cause, because he had recently shown that dried milk subjected to high temperature still retained its antiscorbutic qualities.

Second Day—Thursday, June 12

Relief Work in France.—Dr. W. S. Ramsey of St. Paul made this presentation. He stated that he had arrived in this country only two days ago after having been in France for a year. He described the conditions among the refugees when he arrived in France. His special work had been the organization of relief work in the sector in which Rouen was located. They had there from 5,000 to 10,000 Belgian refugees and from 25,000 to 30,000 French refugees, so that great overcrowding prevailed everywhere in that locality. His first undertaking was the establishment of a dispensary in which he had a French personnel, as he had refused to take in any Americans. Many of the children were very poorly nourished and impetigo was very prevalent among them. He described the way in which he had gained the cooperation of the mayor of the city, and described how he succeeded in winning the support of the midwives. The midwives in that locality cared for about 90 per cent. of the confinement cases and were strongly organized, and the social workers soon found that they could not do their work effectively with the antagonism of these women, so he sent for their leader and explained what he was trying to do for the women and children and succeeded in gaining their cooperation. He had also succeeded in interesting religious workers and in gaining the collaboration of one thousand factory workers. He described the way in which he had succeeded in establishing a maternity hospital, a social service work, a training school for social service workers, a prenatal clinic, playgrounds, and dental clinics, and a farm colony. Much of this work would be permanent in character.

Dr. J. P. Sedgewick said that Dr. Ramsey had not said much about the kind of illness encountered among the refugees. It was largely impetigo and allied troubles. When one took into consideration the difficulties with which Dr. Ramsey had to contend he thought they must all agree that he had done more than any of the other child welfare workers who had gone to France, and he had done it with very little aid from the Red Cross. He had succeeded in getting the French to furnish much assistance. If he had done as much as Dr. Ramsey had done he should feel very proud indeed.

Hemangioendotheliosarcoma of the Liver: A Disease of Early Life.—Dr. John A. Foote of Washington, D. C., presented this communication, in which he stated that he had recently reported a case of hemangiothelioma of the liver in an infant, and cited four others previously reported. A study also of the histories of a number of so-called primary hemangiosarcomas of the liver in infants led him to the conclusion that some of these at least were really hemangioendotheliomas and should be so classified. Because of the confusion in terminology, and since, according to Adami, the actively growing tumors of transitional lepidic character had also from this standpoint to be considered as sarcomatous, the writer had suggested that all malignant hemangiomas of this type be called hemangioendotheliosarcoma. He summed up the information gained from the study of ten cases from which he concluded that hemoagioendotheliosarcoma of the liver was a congenital disease manifesting itself by an enlargement of the liver and some digestive disturbances within three months after birth, and caused by rapid and unrestrained proliferation of the endothelium of the liver capillaries, causing the formation of nodules on the surface of and within the liver and a rapid and progressive increase in the size of that organ, with a fatal termination usually before the sixth month as a result of pressure and obliteration of liver tissue. Jaundice and ascites were not usually observed and metastases were not found. The liver was purplish in color, studded with nodules varying in size from a millet seed to an egg. Some of the nodules were confluent. These nodules were lighter in color than the surrounding tissue, and were also seen throughout the liver in cut sections, as dark red in the center surrounded by a lighter colored ring. Histologically the liver showed an infiltration of the more normal areas with small round cells. In places the liver cells were distorted, atrophied, and vacuolated. The interlobular connective tissue was increased. The smaller blood vessels were choked with large endothelial cells, some showing mitotic figures. The nodules were surrounded with a fibrous area of compressed liver tissue. In some places this fibrous band showed laminae containing degenerated liver cells. The larger nodules were packed with large round or irregular cells with large nuclei, some areas resembling myxosarcoma. Giant cells and neutrophiles were also seen in some areas. Hemorrhagic areas were also noticeable in some fields.

Observations on the Spinal Fluid of Acute Disease.—Dr. William W. Herrick of New York and Dr. Arthur M. Dannenberg of Philadelphia, presented this paper which gave the results of a study of the meningealchoroidal complex in relation to miscellaneous acute diseases, other than meninigitis and poliomyelitis. After reviewing known facts about the anatomy, physiology and pathology they stated that headache, irritability, hyperesthesia, exaggerated reflex activity and delirium, were inaugural features of perhaps the majority of acute infections of any degree of severity. Only when these symptoms of meningeal irritation were prolonged and severe did they ordinarily attract attention. Recorded determinations of globulin, sell counts, etc., in cases of meningismus, were surprisingly few. The cerebrospinal fluid of pneumonia had been fairly well studied by Voisin. Others have found pleocytosis, globulin increase, and pressure changes in isolated examples, or rarely in a small series of cases of scarlet fever, mumps,

enteric fever, pertussis, measles, rabies, diphtheria, sepsis with or without meningismus. The writers had examined the cerebrospinal fluid of over 100 miscellaneous medical conditions with symptoms of meningeal irritation, and had correlated their findings with other clinical and laboratory features of the diseases studied —as temperature, leucocytosis in the blood, degree of meningeal irritation and prognosis. No very direct relation of the reaction of the subarachnoid system to any of these features is apparent. Of 12 cases of labor pneumonia examined, 7 gave a cellular reaction in the cerebrospinal fluid of from 12 to 200 cells; 8 had globulin increase. In 14 cases of bronchopneumonia, 5 had pleocytosis of from 12 to 50 cells. Of 14 cases of influenza, 5 showed from 14 to 40 cells. But 3 had globulin increase. Three cases of follicular tonsilitis had pleocytosis, one showing 172 cells. Of 28 miscellaneous acute medical conditions, 17 showed cerebrospinal fluid pleocytosis, 4 globulin increase. Among these were examples of sepsis, scarlet fever, smallpox, and measles. The writers concluded from a review of the literature and personal study of 76 cases not resulting in meningitis that beyond question the cerebrospinal fluid often gave evidence, in increased pressure, pleocytosis, and heightened globulin content, of a reaction on the part of the leptomeninges to the infective agents or toxins of a large number of miscellaneous acute diseases, not ordinarily causing true meningitis. These diseases were lobar and bronchopneumonia, influenza, tonsillitis; the exanthemata, scarlet fever, measles, variola; herpes zoster, parotitis, enteric fever, sepsis, arthritis, pleurisy, migraine, reaction to typhoid inoculation and others. The cerebrospinal fluid showed variation from the normal in about one-third of the cases studied. Most, but by no means, all of the cases with subarachnoid reaction had clinical meningismus (Meningitis serosa, Dupre). On the other hand, many examples of meningismus were without pronounced changes in the cerebrospinal fluid. The greatest caution should be used in making a diagnosis of meningitis or poliomyelitis from fever, meningismus, and the changes in the cerebrospinal fluid mentioned. Cases with less than 100 cells should be viewed with skepticism, unless clinical, epidemiological, or other laboratory evidence was decisive.

Quantitative and Qualitative Changes in the Cerebrospinal Fluid and Their Significance.—Dr. Abraham Levinson of Chicago stated that this study was undertaken with a view to finding out whether there were any changes in the spinal fluid in meningism, chemical or physicochemical in nature, and what these changes were both qualitatively and quantitatively. Among 155 cases that presented some form of meningeal involvement they had been able to secure spinal fluids in 100 cases of meningism, in which the symptoms soon subsided and the miningism disappeared. All of these 100 cases showed an increase in the amout of prenssure of the cerebrospinal fluid. They did not find very many normal spial fluids among these, as no case was subjected to lumbar puncture unless the indications were very definite. In this series he had found the pressure varying from 200 to 700 mm. while 90 mm. was the normal. They had used an apparatus which permitted no loss of fluid. The normal spinal fluid was practically neutral, but on standing became more alkaline, and hence in making observations on spinal fluids one must take into account the length of time the fluid had been standing. They had investigated the electrical discharge of cerebrospinal fluid protein; the behavior of the spinal fluid toward precipitants; the hydrogen-ion concentration and alkaline reserve, and had studied the changes in the fluid in various forms of meningitis. Acidosis seemed to have no influence on the hydrogen-ion content and the alkaline reserve. The quantity of the protein in the cerebrospinal fluid was not as important as the quality. There were certain quantitative and qualitative changes that were of diagnostic value. The alkaline reserve was lower in tuberculous meningitis than in suppurative meningitis, being a little below normal. Since the cerebrospinal fluid was a fluid of the body it was reasonable to believe that whenever there was retention of a chemical substance in the body there would be an increase of those substances in the spinal fluid. For instance in nephritis there would be an increase in chloride retention and there would be a corresponding increase in the chlorine in the spinal fluid; in uremia one would expect to find an increase in the amount of urea in the spinal fluid; in glycosuria one would expect an increase in sugar. The cerebrospinal fluid was influenced by the blood in the cranium. Any irritation reaching the brain would accelerate the circulation in the cranium and this would be accompanied by increased pressure and an increased amount of blood in the subarachnoid space which would affect the spinal fluid. The amount of precipitin was a useful diagnostic feature in distinguishing between tuberculous and suppurative meningitis. The spinal fluid of nearly all cases if allowed to stand showed a precipitin while in cases of meningism there was no sediment in the spinal fluid on standing. In the classification of spinal fluid changes both qualitative and quantitative changes must be taken into account. There was no evidence of acidosis in meningism. The changes in the spinal fluid were due to mechanical causes, and included changes in the chemical and chemicophysical nature and in the cytology. The changes that occurred in the course of metabolic disease were shown by the spinal fluid by increase in chlorides in nephritis, of sugar in diabetes, and of urea in uremia.

Dr. Charles Gilmore Kerley of New York said he was sure the entire Section thanked Dr. Herrick and Dr. Levinson for having left their section in order to read these very highly scientific papers to them. These papers were valuable in establishing something definite in our knowledge of the relation of pathogenesis to the cerebrospinal fluid. They knew that there was an increased cell count and a positive globulin in pneumonia, scarlet fever, and mumps. Their knowledge in reference to the spinal fluid in may other conditions was very indefinite. The finding of a cell count of 172 in tonsillitis, of 200 in pneumonia, and of over 40 in a large number of other disorders must have a very direct clinical value. It was of great importance to know that there must be a much larger cell count than had hitherto been thought necessary before deciding that one was dealing with a particular disease. This knowledge would have been of the greatest value in the late epidemic of poliomyelitis when it was given out that a cell count of over ten established the diagnosis of poliomyelitis. A tonsillitis with a cell count of 173 would have landed the patient in a poliomyelitis hospital. There was no doubt but that during the epidemic many cases of poliomyelitis were wrongly diagnosed because of the lack of just such information as had been given them this afternoon.

Dr. Isaac Abt of Chicago said that Dr. Levinson's paper had opened up a new and fertile field. He thought they had not yet settled the question of the cell count. With reference to the term meningismus, we ought to define just what was meant. They all saw cases with definite meningeal symptoms in conditions such as typhoid fever and these meningeal symptoms would disappear and the disease would continue and run its course. Of course in the spinal fluid of such cases there might be some slight and insignificant changes but one would never find the changes that were present in true meningitis. The point to be emphasized was that the spinal fluid was a body fluid and reflected the changes going on in the organism just as did the other fluids of the body.

Dr. W. S. Ramsey of St. Paul said he had not heard a paper for years that was so beneficial as both of these papers were. They demonstrated what we had supposed for several years, namely, that there was an increased intercranial pressure both in cases in which one found real bacterial infection and where one did not. During the epidemic of poliomyelitis there was an epidemic of that disease in Norway and Sweden and the doctors did not know with what they were dealing and a variety of forms of poliomyelitis were demonstrated which were designated meningitis serosa. He had found one or two cases with all the symptoms of severe meningitis and after removing the spinal fluid that was under pressure those cases became normal almost at once and the fluids were completely sterile. It was difficult to say whether those cases were a type of poliomyelitis or whether they simply gave the signs of poliomyelitis as a result of pressure. The most practical thing to know was that one got an increased pressure in all sorts of conditions. Dr. Ramsey cited several

cases of conditions in which there were meningeal symptoms that lasted but a brief time and then cleared up and that served to illustrate that we frequently met with cases giving the symptoms of meningitis and which could not be differentiated except by lumbar puncture.

Dr. Alfred F. Hess of New York said that the most interesting part of this discussion had been with reference to meningismus which must have bothered most clinicians for many years. On this question the papers differed absolutely. The first paper stated that changes were found in the spinal fluid in meningism and the second stated that changes were not found in the cell count and chemistry. In view of this difference of opinion it might be worth while to say a few words in regard to the work of the Bureau of Laboratories of New York City. Dr. Neal had been studying spinal fluids for six or seven years and her results might be summarized by saying that in the examination of six or seven hundred cases of miningism during this period she found the cell counts normal in almost all these cases of meningism and the chemical examinations were normal in the cases of meningism except under certain circumstances as, for instance, in convulsions, especially with whooping cough, and in cases in which there was a suppurative condition near the meninges, as an otitis medial continuing for a week or ten days. A point he wished particularly to bring out was that in the acute cases running one or two days one kind of cell count would be found and those cases that had been running for a week or more would have a cell count resembling meningitis.

Dr. H. L. F. Locke of Hartford, Conn., stated that they had found that in meningism the cell changes were only of a minor character but where puncture was delayed five, six or seven days they had found a moderate increase in the number of cells and the amount of globulin. The reason was that cerebral congestion delayed the absorption of the fluid in these cases, and the longer these cases were allowed to go without puncture the more likely it was that changes would be found in the spinal fluid.

Dr. Herman Schwartz of New York expressed surprise that if the puncture was done early a cell count of 170 should have been found in a case of tonsilitis and he was not entirely convinced that a cell count of 60 or 70 was not of some value. Usually one found the sugar in the blood increased in certain inflammatory conditions but in most cases in which were real inflammatory conditions present in the brain the sugar was also increased in the spinal fluid.

Dr. Fritz B. Talbot of Boston said there was one point these papers brought out very clearly and that was that the same mistake had been made in this phase of medicine that had been made in all phases of medicine, namely, that they first studied the pathology and did not study the normal. It was very encouraging to see so much normal data being recorded. He hoped this tendency would be emphasized and developed.

Dr. W. R. Sisson of Boston spoke of his experience at Camp Lee in Michigan when the first cases of encephalitis lethargica occurred. They had at the same time a large number of cases of mumps, many fulminating in type, and a large number giving meningeal symptoms. He found a pleocytosis of 200 cells and they came to recognize mumps as not only involving the parotid gland and testicles but also the meninges and they noted that the presence of mononuclear cells had some significance; whether they were of endothelial origin or not they represented some reaction to bacterial infection.

Dr. Morse of New Haven said that in cases with meningeal symptoms they first made a blood culture and they had found positive cultures in a considerable number of cases. That led them to do a lumbar puncture and they had made cultures of the spinal fluid and found the meningococcus in considerable numbers in the spinal fluid, but the organisms were present in some cases that did not show meningeal symptoms. This suggested the possibility that the organisms might get into the spinal fluid in a greater number of instances than we had recognized without setting up inflammatory changes in the meninges which could be grossly recognized though there might be a response in the cells.

Capt. Arthur M. Dannenberg of Philadelphia said that in answer to the question whether the spinal fluids were examined early or later on, all were done immediately on the admission of the patient to the hospital, in from fifteen minutes to one hour. In the course of an acute tonsilitis the examination might be made after the patient had been in the hospital for several days and the lumbar puncture was an afterthought.

Dr. Herrick, in closing, said the English speaking clinician was behind the French and German clinician in regard to the investigation of this subject. A number of French and German investigators had shown that in a variety of acute infections there was a positive reaction as shown by changes in the cerebrospinal fluid. It was in only about 30 per cent. of their cases of meningism that these changes in the spinal fluid were found; that left a considerable majority without reaction. The work of Dr. Levinson was interesting as pointing out the possibilities of a detailed study of the chemistry of the cerebrospinal fluid. In the last analysis the diagnosis depended upon the demonstration of a bacterial infection. An increased pressure was an inaugural feature in acute infections and was defensive as it effected an increased consolidation of the meningeal choroid plexus. The practical point was that cases with less than 100 cells were usually not to be regarded too seriously unless one could demonstrate the etiological agent concerned.

Dr. Levinson said the discussion had brought out the timeliness of emphasizing two points. He believed that in medicine there was a tendency to generalization and the time had come when this tendency should be combatted. They had been inclined to place a little too much emphasis on the cytology of the spinal fluid and the time seemed to have come when they should give more attention to the chemical and chemicophysical side. They should see the spinal fluid as part of the normal organism, as a body fluid regulated by all the factors that were regulating the blood stream. If the blood pressure in the cranium was increased they must expect an increased spinal fluid pressure, and changes in the chemistry of the spinal fluid in uremia, diabetes, and other conditions. A study of the spinal fluid must not be confined to the investigation of the cytology, but must include the chemistry, chemicophysical characteristics, and the bacteriology, all taken into connection with the clinical findings.

Pneumonia in Infancy and Childhood Without Physical Signs.—Dr. Rowland G. Freeman of New York made this presentation which he illustrated with lantern slides. He stated that the question whether there could be a real pneumonia without physical signs had not been discussed and this possibility was not definitely stated in textbooks. The best opinion was that in children a positive diagnosis could be made without the presence of physical signs in the chest when there existed several of the following symptoms: Fever, overactivity of the alæ nasi; a pneumonic type of respiration, and a pause at the end of inspiration accompanied by an expiratory grunt; a relation between respiration and pulse of approximately one to three; rigidity of the lower extremities, and an effort on the part of the child to protect a sore chest. Notwithstanding this, in consultation he had found men surprised when a diagnosis of pneumonia was made without physical signs. It was of great importance that the possibility of the existence of pneumonia without physical signs be recognized, especially in a child who had acquired a respiratory infection where the ears had been involved and the temperature was persistently high and the question arose as to whether a mastoid operation should be done. Since the adoption of the use of the *x*-ray in hospital practice pneumonia had been found where no physical signs of its existence had been discovered and even after its discovery by the *x*-ray the physical signs were not found. There was urgent need for an *x*-ray apparatus that could be used in private houses; Dr. Freeman cited three illustrative cases all of which showed approximately the same area of the right lung involved and the consolidation in none of the cases ran up to the apex. It might be considered an involvement of the right middle lobe. If, however, it was the right middle lobe it should be possible to obtain signs over the anterior portion of the chest. It seemed to him much

more probable that the involvement was of the right upper lobe and that the signs were obscured because in order to hear them one would have to listen through the right scapula. It was not remarkable that no signs could be detected in the right axilla.

Dr. W. S. RAMSEY of St. Paul said that there was no question but that not infrequently pneumonia occurred without physical signs and it might go on to resolution without the signs being found. These might be central pneumonias. Dr. Freeman had mentioned the one sign by which to recognize pneumonia without physical signs and that was the pause at the end of inspiration and the expiratory grunt. One seldom had pneumonia without this characteristic breathing.

Dr. ERNEST ZUEBLIN of Cincinnati agreed that the physical signs in pneumonia might be more or less missing. In the recent epidemic they had had their attention drawn to a particular shadow in the intrascapular region which would correspond to the right middle lobe or the apices of both lower lobes; there might exist also a difference in dullness and the whispered voice might be increased together with a harsh expiration. Usually the shadows could be followed with the fluoroscope.

Dr. CHARLES G. KERLEY stated that these cases were most instructive and suggested that if a great many other diseases were subjected to *x*-ray examination much additional light might be thrown upon them. His recent observations on persistent chronic gastrointestinal disorders served to illustrate this point.

Dr. LAURENCE R. DEBUYS said he remembered Dr. Freeman's paper on this subject a few years ago and since that time his experience was very much as follows: Many cases of pneumonia went on to convalescence without physical findings. This was due to the fact that consolidation did not extend to the hilum. The plan he used was whenever he found the clinical picture of pneumonia and no physical signs was to arrive at the diagnosis by exclusion.

Dr. WALL of Washington said someone had asked for the symptomatology in these cases of pneumonia without physical signs. They had observed two types of dyspnea in children, the dyspnea of asthmatic bronchitis and acidosis and that of pneumonia. They had observed a dyspnea which was absolutely central in origin, associated with toxemia, pyrexia, or hyperpyrexia. It had been their observation that the dyspnea in pneumonia was a more or less stable condition and was unaffected by sleep.

Dr. GODFREY R. PISEK of New York said that if these cases of pneumonia without physical signs were carefully observed at stated periods he thought that some physical signs would be found. If these cases were carefully watched one usually got the signs before the drop in temperature. Sometimes the signs might be present only a few hours and then disappear.

Dr. LOUIS FISCHER of New York called attention to the fact that in addition to the *x*-ray, which was not adapted to private practice, the differential blood count was valuable. In pneumonia one found a high polynuclear percentage and a high leucocyte count, the polynuclear count running up to 70, 80 or 90, and with this finding one could establish a diagnosis even without physical signs.

Dr. ZUEBLIN spoke of the possibility of there being a pleurisy. If there was a pleural exudate it would not clear up so quickly as these cases had done. These cases did not look like pneumonia. There was no marked acceleration of respiration. There was a high blood count but none of the other symptoms that one looked for.

A Comparative Study of the Early and Late Secondary Complications of Influenza and Influenza-Pneumonia as Seen in the Army with Those of Infants and Children in Civil Practice.—Dr. JULIUS HESS of Chicago presented this communication which was based on the replies to a questionnaire received from forty-five teachers of diseases of children in practically all parts of the United States. There were in all data with reference to 3117 cases. In the analysis to classify these cases they had been divided into three groups, private practice, hospital, and institutional cases. The analysis included a comparison of the morbidity, nature, and severity of complications in the adult, child and infant, and of the relative severity and character of the pandemic in different sections of the United States and foreign countries, in children and infants. A few of the many points brought out were that there was a tendency toward family contagion. In children there was less tendency toward serious complications than in adults in the same family. Leucocytosis was a prominent finding, there being as high as two to four thousand cells per cm. The blood pressure in uncomplicated influenza of moderate degree was systolic from 104 to 126; there was an average of 42 pulse pressure. Adults and children showed practically the same results in reference to blood pressure. The percentage of children developing pneumonia varied greatly. It seemed that children were more susceptible to pneumonia in the first wave and infants in the second. Children on the whole seemed to show a lower morbidity and mortality, 15 to 56 per cent. In the army the incidence averaged 15 to 25 per cent. The morbidity was higher among children during the second wave than during the first in private practice, while the reverse was true in the lower classes. The most frequent complications were otitis media and empyema. The empyema occurred in the subscapular region in one or both lobes in 75 per cent. of the cases. All agreed that second attacks were rare. They, however, had had three distinct secondary attacks at the Michael Reese Hospital. Other frequent complications mentioned were laryngitis, epistaxis, and sinusitis. Severe jaundice had occurred in one per cent. of all cases, with swelling and induration of the liver. Cardiac deaths were frequent in adults. In most autopsies in soldiers the right heart was found dilated. Most reports stated that this finding was not common in children. Endocarditis was a rare complication. A considerable number of systolic murmurs were noted that were absolutely due to the epidemic. Emphysema was a rare complication in children. Some cases showed meningism, with the cerebrospinal fluid under pressure, and a slight or moderate increase in globulin and a cell count rarely exceeding 50. Encephalitis was rare and was only seen late in the epidemic. Abdominal complications, pseudo appendicitis and tympany, were rare. A persistent cough was one of the most common complications. Severe secondary anemia and chronic forms of anemia were comparatively rare in children. Secondary anemia in soldiers was a rather common finding. Pulmonary tuberculosis had not been noted to date as following influenza. They had come to the conclusion that pulmonary tuberculosis was an infrequent complication, nevertheless in the absence of marked changes the diagnosis of pulmonary tuberculosis could only be made by careful study. Among the hospital cases there were 1,085 recorded with a mortality of 9.2 per cent. In private practice the mortality among children was 2.4 per cent. and 4.8 among infants. The mortality of hospital cases was from two to four times as high. In well organized institutions the mortality had been exceptionally low. The general impression from this study was that influenza in children was much less severe than in adults and that in private practice the prognosis was better than in hospitals. Pneumonia and secondary pneumonia in children was less severe than in adults. Influenza was a disease involving the respiratory system with a special predilection to the production of capillary bronchitis or lobar pneumonia.

(*To be continued.*)

Silver Nitrate Poisoning Not an Occupational Disease.—The Illinois Appellate Court holds that silver nitrate poisoning is not an occupational disease and is not incident to the making of mirror glass. In order for silver nitrate poisoning to be peculiar to the work or process carried on in the manufacture of mirrors in a factory, or to be incident to the work or process, so as to constitute the disease an occupational disease within section 1 of the Illinois Occupational Diseases Act, it must have happened before and must be such a disease as those familiar with the process would realize was likely to occur.—Arnell v. Superior Mirror Co., 210 Ill. App. 486.

INDEX.

A

Abdomen, distended, radiological diagnosis with a new method, 207.

Abdominal catastrophes, influenzal, 662; complications of the influenza epidemic at Camp Custer, Mich., 577; diagnosis, a new radiological procedure for, 207, 798; phenomena in gunshot injuries of the spine, 338; section, purgation before and after, 261.

Abortion, artificial, in antiquity, 108.

Abrams, Albert: the medical treatment of appendicitis, 484; the splenic reflexes of Abrams in the treatment of syphilis, 96.

Abscess, cerebellar, report of successful operation for, by obliteration of the lateral sinus and exploration and drainage through its inner wall and anterior surface of cerebellum, 274; large pelvic, due to foreign body in the posterior vaginal wall, 421; perisinus, a case of acute mastoiditis with, following influenza pneumonia, operation performed under novocaine and morphine anesthesia, 323; perisinus and epidural mastoid, subsequent to influenza, report of five cases, 819; pulmonary, following aspiration of sea water, 302.

Acanthosis nigricans in the cancerous, 537.

Accident and pre-existing disease, strangulated hernia, 733; find carelessness cause of, 414; heat prostration an, 486; industrial, an analysis of two hundred and sixteen, 685; industrial, causation and prevention of, 745; insurance, presumption against suicide, 63; poison voluntarily or involuntarily taken, 733; policy, meaning of "infection" in, 150; traffic, 656; where sunstroke held an, 63.

Acclimatization, as to, 569.

Acid, homogentisic, as a chromogenous product, 118.

Acidosis and operation, 833; diagnosis of, 741; iodine urine test for, 925; of epidemic influenza, alkali treatment applied to the, 661; simple urine test for, 404.

Acne, cheloid, of the neck, pathology of, 443.

Acromegalia, a familial affection resembling, involving the skeleton more particularly, 789.

Act, Harrison anti-narcotic, construction of, 638; held valid, 1100; see also *Drug*.

Addison's disease and sclerodermia, 378.

Adenomata of the sudoriparous glands, 1069.

Adenomyomata containing uterine mucosa, distribution of, 977.

Adrenalin, value of provocative injection of, in latent malaria, 252.

Advertising, modern, and the nostrum evil, 122; physicians, moving against, 699.

Aerophagy, the minor symptoms of, 886.

Albumin, heterospecific, the prevention of the phenomena of hypersensibility in the parenteral exhibition of 293.

Albumosuria, Bence-Jones', with lymphocytic leucocythemia, a case of, 206.

Alcohol, glycerine and, the purchase of, 71.

Alcoholic drinks, sale of, 1014.

Alcoholism, chronic, in Switzerland, 965.

Alkali treatment applied to the acidosis of epidemic influenza, 661.

Alkalinization of infants' food, deleterious effects of, 1115.

Alkaloids, isoquinolinic, (Isochinolin-alkaloid) of opium and emetine, choice of, and their therapeutic uses, 378.

Allen's, Major H. R., instantaneous method of reshaping tool handles so that they may be used by deformed or crippled hands, 269.

Allen, Walter C.: use of musk in pneumonia; not a scientific drug, and subject to gross substitution, 356.

Alopecia, post-influenzal, 402, 496.

Amaurosis from quinine synthetics, nature of, 368.

Ambulance corps, demobilization of the, 576.

Ambulatory chair, an, 260.

America, the spas of, 448.

American board of ophthalmic examinations, the, 370; expeditionary forces, some experiences with U. S. A. base hospital No. 37, 945; field service, closing of the, 748; gifts to Portsmouth, 450; hospital in London, 971; journal of care for cripples, the, 330; memorial, an, 450; peace mission, quarters for the, 114; Red Cross, see *Red Cross*.

Amputation stumps for voluntary movement of the arm prostheses, formation of, 162.

Amputations, cinematic, the utilization of the muscles of a stump to actuate artificial limbs, 1004.

Analgesia, visceral, in tabes dorsalis, 665.

Anaphylactic shock, acute, slow intravenous injection of antiserum to prevent, 291.

Anemia, alimental, in nurslings and early childhood, 797; aplastic, 253; chlorotic type of, in infants and children, 171; diagnostic significance of urobilinogen in the differentiation of cancer and, 536; severe, of pregnancy and the postpartum state, observations on the, 251; symposium on, at annual meeting of medical society of the State of New York, 932.

Anesthesia, 300; and eutocia, 981; local two hundred and fifty major operation under, 135, 167; sacral, a preliminary report, 991; spinal, has, established itself? 875.

Anesthetists, nurses as, 966.

Aneurysm of the abdominal aorta, diagnosis of, particularly radiodiagnosis, 1111.

Angina, pemphigoid, in influenza, 285.

Animated diagram in femoral hernia operation, remarks on the value of, 258; Taylor's technique, tendon transplantation for flat foot, 259.

Anthrax cured by neosalvarsan, 201.

Antimonium tartaratum, intravenous injections of, in bilharziosis, 118.

Antiserum, slow intravenous injection of, to prevent acute anaphylactic shock, 291.

Antitoxin, studies on a toxin of gas edema and its, 581; the treatment of tetanus by injections of, in the lateral ventricle, 619.

Antituberculosis campaign launched, 967.

Aorta, spontaneous rupture of a healthy, can it occur, and how does it take place? 163.

Apoplexy, suprarenal, the clinical picture of, 253.

Appendectomy, a new incision for, 638.

Appendicitis, medical treatment of, 484; acute, in the aged, 611; acute, pneumonia, acute empyema, pneumococcic peritonitis, their differential diagnosis, 102; chronic, notes on two signs in, 298; chronic, study of postoperative end results, 978; chronic, the two most important signs in, 55, 88.

Appendix, human, function of the, 293; the migratory, 497.

Appliances, safety, permanent exhibition of, 744.

Army ambulance service, United States, the, 375; avitaminoses in the, 364; death rate in, from battle and disease, 365; deaths in the, 789; distinguished services, citations for, 699; doctors accused of negligence, 605; experiences of a urologist with the fighting forces in France, 757; health of the, 440; honors for service men, 927; industrial, our duty to the, 260; leaves area at Nice, 532; laboratories, future of, 108; laboratory and the prevention of infectious disease, the, 996; little insanity in the, 740; losses in the United States forces, 282; malignant grippe in the, 281; medical officer, the return of the, 664; poliomyelitis in the, 501; social disease in the, 383; some notes on the examination of five thousand selected service registrants, 300; suicides in, 522; urological department, administration of, 759.

Arsenic in syphilis, administration of, 422; quinine and, prevention of grippe by, 34.

Arsphenamine, administration of, 791.

Arterial pressure, high, unusual tolerance, especially in women, to, 1076.

Arteriosclerosis, juvenile, 618; pathogenesis of, 535.

Arthritides, sporotrichosis, 923.

Arthritis, tonsilectomy in myositis and, 795.

Artificial limbs, cinematic amputations, the utilization of the muscles of a stump to actuate, 1004; see also, *Prostheses*.

Aspirin, incompatibility of quinine and, 69.

Asthenia, cardiac, a case of mitral lesion with, the ventricular weakness being demonstrable by the venous pulse, 33; neurocirculatory, N. C. A., 1068.

Asthma, a theory of, as confirmed by nearly four hundred cases, successfully treated, 393; bronchial, a clinical study of four hundred patients with, 421; of nasal origin, 580.
Ascites, a new operation for, 456.
Atrophy, tabetic optic, the treatment of general paralysis of the Insane by the introduction of salvarsanized serum into the lateral ventricle and a suggestion for the arrest of, by the same means, 839.
Aulde, John: dietary deficiency and disease, practical pointers on health maintenance, 518.
Auscultatory percussion, 561.
Autointoxication symptoms, origin of so-called, 116.
Autolysates, organ extracts and, action of, 163.
Automobile fatalities in 1918, 70; plague in Washington, medical and legal aspects of the, 858.
Autopsy, necessity for demand for, 486.
Autoserotherapy of influenza, 743.
Autoserum treatment of chorea, 1070.
Aviation candidates, observations on the medical examination of, 116; medical aspects of, 454; problems of, research work on the, 545; recruiting for, 113; sanitary, on the edge of the Sahara, 659.
Aviators, nasal obstruction in, 376; the ear and the, 211; vestibular reactions in five hundred and forty-one, 496.
Avitaminoses in the army, 364.

Deafmute, data about the, 743.
Deafness, acquired, a discussion of some social and economic problems resulting from, 713; acquired, mental and spiritual readjustments of, 713; acquired, practical aspects of readjustment of, 713; simulated the use of Barany's drum and reflex winking in the diagnosis of, 709.
Death, an inquiry into the reliability of diagnosis of diseases causing, 125; following an intravenous injection, 409; from drowning, a short historical sketch on, 232; from germ infection, 521; major general of the, 349; rate, English, exceeds birth rate, 527; rate, French, far exceeds birth rate, 331; rate in army from battle and disease, 365; rate in Paris, increasing 576; rate, Pennsylvania, for 1918, 154.
Debility, myocardial, diagnosis of, 1110.
Deficiency disease pathogenesis of, 499; diseases, remarks on the pathogenesis of, and on pellagra, 974.
Delineator, intestinal, *x*-ray visualization of the gut by means of a new, 509.
Delinquency, juvenile, in war, 286.
"Délire de rêve," Lasegue's, in a menstrual psychosis in a debile, 77.
Delivery, normal, rare complication following, 458.
Dermatitis coccidiosa, report of a case of, 361.
Dermatophobia, 608.
Demineralization from gassing, 833.
Demobilization and the venereal problem, 158; and venereal disease, 326.
Demobilized practitioner, the position of the, 614.
Democracy and public health, 124.
Dental caries, incidence of, 71; disease, prevention of, 284; medical and, professions, the need of cooperation between the, 952; practice, British, troubles of, 531.
Dentist, famous, death of a, 614.
Diabetes mellitus, 615.
Diabetic coma, prevention and treatment of, 336.
Diaphragm, functional paralysis of the, in two cases with acceleration of respiration, 663.
Dichloramine-T, chlorine, and catgut, 104.
Dickson, John D., Edwin Henry Schorer, F. D. Clark, Raymond Sanderson, Frank M. Huntoon: pneumonia and empyema in the late winter of 1917-1918, 673.
Diet, milk, blood changes induced by a, 881.
Dietary deficiency and disease, practical pointers on health maintenance, 518.
Dietetics, medical, a course in, 1051.
Digestive disturbances due to breast milk too rich in fat, 665; psychoses, a study of the, 753.
Dilatation, acute, of the stomach, 366, 529; of the esophagus, case of cardiospasm with, 164.
Diphtheria, advantages of combined serum treatment in, 118; bacillus, has normal horse serum an action on experimental injection of the guinea-pig with the, 751; bacteriological diagnosis of, 798, gains ground in Sing Sing, 526; increases in New York City, 412; serum treatment of, 292; toxin-antitoxin, the active immunization of children under eighteen months of age with, 462; treatment of, with plain horse serum, 33; wound, on, 501.
Directory, the new, 69.
Disabled civilians, future policy in dealing with, some conclusions from experience, 142; men, instructors wanted for, 241; soldiers, see *Soldiers;* reeducation of the, see *Reeducation;* rehabilitation of the, see *Rehabilitation.*
Discussion fiend, the, 922.
Divers' disease, 618.
Diverticula, congenital, of the intestines, report of case of a tumor growing from the tip of a congenital diverticulum in the lower sigmoid region, 297.
Doctors and the changing order, 849; charge illegal conspiracy, 70; German, a plethora of, 1012; hospital, pensions to, 702.
Dogs' protection bill, see *Bill.*
Doty, Alvah H.: outlook and problems of public health, 1037.
Drainage, abdominal, after laparotomy, 535; gynecological pelvic, its indications, methods, and materials, 300; thoracic, see *Thoracic.*
Drowning, a short historical sketch on death from, 232.
Drug addiction, government survey of, 700; addiction, narcotic, proposed discussion of, 966; addiction, report of special committee of the medical society of the state of New York on, 846; addicts clinic for, 655; addicts, clinics for treatment of, 612; addicts may be identified, 924; addicts, New York's, 446; anti-narcotic, investigation, report of committee of medical society of the county of New York, 86; campaign in New York, 700; clerks form union, 145; committee, mayor to name, 834; control board, Governor of New York State urges abolition of, 155; Harrison act held valid, 1100; Harrison anti-narcotic act, construction of, 638; law, supreme court to define, 110; narcotic, control, enforcing, 246; narcotic, control, the New York State department of, 155; narcotic, law, a loop-hole in, 572; narcotic, question, 968; narcotic, situation, the health commissioner and the, 969; rush for, to meet dry situation, 412; unprofessional conduct in prescribing, 439; users, opposition to finger printing of, 1062.

Druggists object to selling liquor, 445.
Dudley, Professor Emilius C., retirement of, 27.
Duodenal obstruction, chronic, 216; obstruction with duodenojejunostomy, 215; ulcer, perforated, 215.
Duodenectomy, a new method, 749.
Duodenojejunostomy, duodenal obstruction with, 215.
Duodenum, pathological, lantern demonstration of the, a type frequently overlooked, 217.
Dunton, W. R.: occupational therapy and tuberculosis, 942.
Duval, E.: etiology and mechanism of the "prison psychoses." An opinion and some case studies, 6.
Dying declarations, 150.
Dysentery, amebic, myristica (nutmeg) in the treatment of, 354; amebic, study of, 107; complications of, and their treatment, 33; venal changes in, 709.
Dyspepsia, unmotivated nervous, and tuberculosis, 245.

E

Eagleton, Wells P.: an original device for the control of hemorrhage from the large sinuses of the brain by invulsion of the outer wall into the lumen, with report of a successful operation for cerebellar abscess by obliteration of the lateral sinus and exploration and drainage through its inner wall and anterior surface of cerebellum, 274.
Ear and the aviator, the, 211; studies, practical value of, 210.
Earp, S. E.: some of the salient duties of a nurse, 862.
Eczema, seborrheic, of the lower lip with deep central cracking, 438.
Edema, cerebral, from salvarsan, 581; disease and bradycardia, 422; gas, see *Gas edema*; subalimentation and, of famine, 1112.
Education, physical, Columbia university plans new system of, 1105.
Einhorn, Max; jaundice, 1043; *x*-ray visualization of the gut by means of a new intestinal delineator, 509.
Eisenberg, I. C.: the prepuce as grafting material, 514.
Elaiopathia, pathomimic, 26.
Electrocardiography and orthodiagraphy, the importance of the adoption of, as routine measures in the management of disorders of the heart, 1, 38.
Electrotherapeutic work, massage and, in a war hospital, 65.
Emboli, lecture on missiles as, 1018.
Emphysema, mediastinal, a true case of, 1052; tissue, in influenza, 346.
Empyema, abscess, and gangrene of the lung following epidemic influenza, 250; acute pneumonia, acute appendicitis, pneumococcic peritonitis, their differential diagnosis, 102; acute respiratory diseases among troops with especial reference to, 195; following influenzal pneumonia, 291; pneumonia and, in the late winter of 1917-1918, 673; problem, the, 261; remarks concerning the employment of the Dakin solution in cases of, 800; roentgenograms of, 805; treatment of, by the Carrel-Dakin method at the war demonstration hospital, 800; what shall be done with the open chronic suppurations of the chest cavity? 770.
Encephalitis, epidemic influenzal, 442; epidemic, with stupor, 631; lethargica, 887; lethargic, an address on, 161; lethargica and mumps meningitis, 619; lethargica, report on cases requested, 494.
Endamebiasis, intestinal, comparative value of ipecac and its alkaloids in treatment of, 31.
Endocrines, a therapeutic suggestion concerning, 429.
Endometrium changes, symposium on diseases of the uterus, physiology and anatomy of, 977.
England and Wales, the diminishing population of, 703.
Envenomization suggested as etiology of hydrophobia, yellow fever, Rocky Mountain spotted fever and cowpox, 533; suggested as etiology of obscure war diseases, 160.
Epidemic disease, new public health regulations for the control of, 449.
Epidemics after wars, 661; Ambroise Paré on, 523; report of committee of American Public Health association on closing schools as a means of controlling, 127.
Epilepsy, influenza and, 492, 575; national association for the study of, 744; oneiroscopy of, 785; operative treatment of, four cases, 343; studies in, 1112.
Epithelioma of upper lip, excision and cheiloplasty, 215.
Erythema multiforme, as a rheumatic manifestation in children, 427.
Esophageal, bronchoscopic and, cases, five recent, 361.
Esophagus, case of cardiospasm with dilatation of the, 161.
Ether, treatment of peritonitis with, 338, 665.
Eutocia, anesthesia and, 981.
Eventration of the stomach, traumatic, into the left hemithorax, with a clinical picture of hypertensive pneumothorax, 378.
Exanthema of latent typhus fever and malaria, examination of the, according to Weiss' procedure of observation of the capillaries, 618; variola without, 293; varioloform hemorrhagic, during pneumonia, a case of, 253.
Exercise, physical, in later life, 558.
Exhibition, an interesting, 880.
Exophthalmic goiter, see *goiter*.
Exostoses of humerus and tibia, large chondroma of the ribs associated with, 502.
Expert evidence, Colle's fracture, 406; evidence, different schools of thought, 486; evidence, smoking opium, 363; medical cross-examination of, 919; opinion, 439; opinion based on excluded *x*-ray photograph, 919; opinion, basis of, 1100; testimony as to future physical condition, 325; testimony as to value of physicians' services, use of *x*-rays in diagnosis, 1100; testimony, care for child after birth, 406.
Extracts, organ, and autolysates, action of, 163.
Eye, concussion and contusion injuries of the, in warfare, concerning, 544; conditions, distressing general affections traceable to, 279; transmission of infection through the 453.

F

Famine in Germany, the, 456; subalimentation and edema of, 1112.
Faries, John Culbert: a study in rehabilitation of the disabled soldier, 861.
Fat, necrosis, multiple perforations of the anterior wall of the stomach, chronic pancreatitis with, 342.
Fatigue, the reaction of the circulatory system in, 754.
Febrile state, conception of the, 164.
Feebleminded, regulation and care of the, 1067.
Feeblemindedness in Canada, 452.
Feeding, artificial, of athreptic infants, 1114; of the Vienna population, data on the, 253; the sick child, 618.
Ferris, Albert Warren: a case of osteitis deformans, 853.
Fever, blackwater, etiology of, 152; hay, see *Hay fever;* pappataci, in Puerto Rico, 886; periodical, with tibialgia, 208; practical points in the treatment of, 818; Rocky Mountain spotted, see *Rocky Mountain spotted fever;* typhus, see *Typhus fever;* yellow, see *Yellow fever.*
Flavine and B. I. P. P. in war surgery, 106; and Dakin's solution, 21.
Flexion of the great toe, a sign of lesions of the sciatic nerve and its branches, 198.
Fibromyositis or "rheumatic conditions," 1083.
Fibrosarcoma of the skull, 261.
Field, C. Everett; false teeth as a cause of cancer, 275; radium, its present status as surgery's adjunct, 1081.
Figueira's syndrome, 109.
Filter-passing virus, preliminary report on the presence of a, in certain diseases, with especial reference to trench fever, influenza, and nephritis, 420.
Flat foot, exercises for, abstracts of lectures on, 259; tendon transplantation for, (a) animated diagram, Taylor's technique, (b) moving picture of Taylor's operation, (c) moving picture of Leo Mayer's operation, 259.
Fletcher, Horace, bequest to Howard university, 573.
Floculation, the diagnostic value of the cerebrospinal fluid by the procedure of, in cerebrospinal syphilitic lesions, 207.
Food in sufficient quantity to satisfy, value of, 1111.
Foot, deviation from natural function of the, exercises for flat foot, fallacies of so-called arch supports, abstracts from lectures on, 259; flat, see *Flat foot.*
Fox, Elsie: radiographic types of influenzal pneumonias, 513.
Fractures, gunshot, of the jaw, bone grafting in, 162; of the skull, diagnosis, treatment, and end results, 263; radiodiagnosis of the consolidation of, 379; recent retrogressions in the treatment of, 751.
Fraternizing, no, 288.
Friedman, G. A.; the possible spread of influenza through the bedbug, 14.
Friedmann's serum, results obtained in tuberculous patients treated in 1913 with, 423.
Front, surgery of the chest as carried out at the, 423.
Functional restoration, training for by workers in, 856.

G

Galen on simulation, 526.
Gall-bladder, comparatively healthy, are we justified in removing, 263; maglignant papilloma of the, 297.
Gangi's reaction, 24.
Gangrene, gas, see *Gas gangrene.*
Gas edema, bacteriological and serological essentials for the prophylaxis and treatment of, with a polyvalent serum, 1019; studies on a toxin of, and its antitoxin, 581.
Gas gangrene due to infection with a new pathogenic anaerobe, 884.
Gas poisoning in warfare, a study of the effects of so-called mustard gas upon the upper respiratory tract, 312.
hypertrophic stenosis in, 178.
Gassing, demineralization from, 833.
Gastric ulcer, see *Ulcer.*

Infectious disease, the army laboratory and the prevention of infectious disease, 996; the respiratory tract as portal of entry for, 86.

Inflammations, treatment of, with protein bodies and inhibition, 798.

Influenza, 72, 536, 889; a comparison, 52; aboard a man-of-war, a clinical summary, 680; acute, and influenzal bronchopneumonia, the use of vaccines in, 205; advocates serum for, 70; again on increase, 70; and bronchopneumonia, the treatment of by the use of human serum, 541; and epilepsy, 492, 575; and influenza-pneumonia as seen in the army, comparative study of the early and late secondary complications of, with those of infants and children in civil practice, 1119; and nephritis, preliminary report on the presence of a filter-passing virus in certain diseases, with especial reference to trench fever, 120; and pneumonia, the dangers of secondary infection in the ward treatment of, 541; as a complication of pregnancy, 979; at an isolation hospital last summer, 339; aural complications, 890; autoserotherapy of, 743; bacillus, culture of the, 76; bacillus or disease, which should be treated in, 519; bacteriology of, 345; boom in insurance follows, 877; bronchopneumonia, use of human serum in treatment of, 749; cartoons in 1848, 806; clinical observations on, 119; circulatory complications in, notes on the epidemic in the U. S. marine hospital, Stapleton, N. Y., 705; comatose forms of, 490; commission, Illinois, the work of the, 81; committee, joint, 369; data for a history of, 208; disappears from camps, 522; dramatic case of, 537; endemic before 1890, 606; epidemic, the, 34; epidemic and its prevention, the, 532; epidemic, alkali treatment applied to the acidosis of, 661; epidemic at Camp Custer, Mich., abdominal complications of the, 577; epidemic, bacteriological findings in, 492; epidemic, bacteriology of the present, 76; epidemic continues in the United States, 201; epidemic, empyema, abscess, and gangrene of the lung following, 250; epidemic in British Columbia, 705; epidemic, in pregnancy, the occurrence of, 381; epidemic, measures to curb the, 374; epidemic, remarks on, 119; epidemic, report of the committee of the American Public Health Association on administration for relief during the, 82; etiology of, 79, 456; etiology of, a filtrable virus as the cause, with some notes on the culture of the virus by Noguchi's method, 707; etiology and epidemiology of, 456; fatalities in South Africa, 330; grip-like infection in the fall of 1917, a, 755; heart, 710; hemethylenamine and methylene blue in, 379; in a tuberculosis sanatorium, 592, 626; in animals, 423; in army and navy, 22; in Batabanos, 1010; in Bordeaux, 164; in Brazil, 457, 710; in Britain and Spain, 412; in Central America, 27; in Dublin, 29; in Holland, 582; in India, 201; in Mexico City, 508; in Norway, 666; in parturient women, 49; in Puerta Rico, 457; in South Sea Islands, 27, 789; in the far East, 244; increase in 1918 death rate due to, 110; increases, 27; Indians ravaged by, 371; influence of, on the female organs of generation, 755; intravenous injections of camphorated oil in the asphyxiating type of grippe, 293; kidney and, 1061; large doses of camphor, especially in, 119; malignant grippe in the army, 281; masks in Australia, 286; medical complications and sequelae of, 39; meningococcus bronchopneumonia in, 292; mortality in Madrid during the grippe year, 444; no abatement in the prevailing epidemic, 114; nose, throat, and ear affections complicating or following the recent epidemic of so-called, with a ventured interpretation of their significance, 40; nostras, 789; notes on the month of, at a base hospital in France, 594; observations on, 582; organization of forces against, 80; otitis in 1918, 1020; pandemic, defense reactions in, 619; pandemic in France and Spain, the, 253; pandemic of, 831; pathological anatomy of, 536; pemphigoid angina in, 285; perisinus and epidural mastoid abscess subsequent to influenza, report of five cases, 819; Pfeiffer bacillus, production of indol by certain strains of the, 973; pneumonia and, prophylactic inoculation in, 79; possible spread of, through the bedbug, 14; prevention of, by quinine and arsenic, 34; prevention of, report on the, 516; prophylaxis in, 617; pseudo, 654; psychic disturbances during, 423; psychotherapy in, post, 283; ravages Alaska Indians, 1013; reactions of antituberculous immunity in, 1020; remarks on, 666; report of the public health committee of the New York Academy of Medicine on the prevention of, 541; return of the, 615; rôle of the hand in the distribution of, 81; serum, Boston to use, 28; serum treatment of, 293; Spanish, beneficial results of continuous stimulation of the hepatic detoxifying function by mild doses of calomel, 238; Spanish, etiology and treatment of, 436; Spanish, in 1853, 26; spring and fall, 538; still exists in Italy, 76; still prevalent in Paris, 369; studies on the etiological agent of, 618; surgical affections due to, 842; surgical complications and sequelae of, 40; surgical complications in 1,030 cases of, 262; sweeps India and the Belgian Congo, 744; symptomatology of, 346; takes off many nurses, 241; tissue emphysema in, 346; to help Alaska fight, 27; toll in Jamaica, 201; transmitted by indirect contact, 199; toxin, the, tannin and, 666; treatment of, 208, 579; treatment of pulmonary complications of, with calcium and neosalvarsan, 207; treatment of the pandemic of, 379; treatment of severe, with convalescent serum, 77; three clinical types of the current epidemic, 294; value of the "no-good," minor surgery and, 500; visitations of, and its influence on gynecological and obstetrical conditions, 381; Yersin's bacillus and, 368.

Influenzal encephalitis, epidemic, 442; intraabdominal catastrophes, 662; pneumonia, see *Pneumonia;* post, alopecia, 402; post, immunity, 788; injured employee, refusal of, to submit to operation, 280.

Injuries, concussion and contusion, of the eye in warfare, concerning, 544; gunshot, chronic osteomyelitis resulting from, 937; gunshot, loss of bone substance and non-union following, 938; gunshot, of the spine, abdominal phenomena in, 338; joint, mobilization after, 571.

Insanity as a defense in criminal cases, 363; pulmonary tuberculosis and, 205; drink abstinence believed to lessen, 413; moral, the psychology of, 619.

Insufflation, pharyngeal, 805.

Insurance applicant, evidence of impersonation of, 486; boom in, follows influenza, 877; health, see *health insurance;* organizations, a health conference of, 791; policy, physician's indemnity, construction of, 521; social, report of subcommittee of American Medical Association, 1027.

Interallied fellowship of medicine and the Harvard medical unit, the, 332.

Internal auditory canal, extraction of a shrapnel bullet from the, 666; disease due to warfare, the working capacity of subjects with, 885; medicine in New York State, a program for the development of, 893.

Internists, relation of, to military medicine, 1073.

Intestinal delineator, *x*-ray visualization of the gut by means of a new, 509; disturbances in children depending on mechanical agencies, 173; intoxication, acute, the treatment of, 428; obstruction, acute, colostomy for; Balfour sleeve resection; closure of colostomy, carcinoma of the rectosygmoid, 502; obstruction, unusual, three cases of, 458; stasis, chronic, clinical symptoms of, 663; stasis, chronic, what are the indications for operative interference, 578.

Ionization in the treatment of certain types of facial scars, note on the use of, 534.

Ipecac and its alkaloids in treatment of intestinal endamebiasis, comparative value of, 31.

Ireland, the exclusion of, from the operation of the ministry of health bill, 703; the position of, under the ministry of health bill, 746.

J

Jacobi, A.: ad vocem "musk," 447.

Jaundice, 1043.

Jewish Welfare Board, the, 747

Josephson, E. M.: ulnar nerve tenderness in lead poisoning, 205.

Juvenile delinquency, a psychological study of stealing in, 463.

K

Kahn, Alfred: a method for using Dakin's solution for continuously irrigating the mastoid wound, 61.

Kearney, J. A.: distressing general affections traceable to eye conditions, 279.

Keen, W. W.: fellowship with German physicians, 204.

Kennedy, Foster: epidemic encephalitis with stupor, 631.

Kernig's sign in true typhoid fever, 755.

Kidney, insufficient left, and right-sided nephrectomy followed by successful result, 1019; ruptured, suture of, with report of a case, 296; sublimate, 610; suspension of the, a new technique for, 708; the, and influenza, 1061.

Kitchen, J. M. W.: possible benefits of respiratory narcosis in preventing influenzal pneumonia, 657; relating to the possibility of protein split product poisons being formed in market milk, 186; the special treatment that should be given milk intended for infant feeding, 725.

Knapp, Mark L.: a theory of asthma as confirmed by nearly four hundred cases, successfully treated, 393.

Krumbhaar, E. B., and S. Bradbury: notes on a month of influenza at a base hospital in France, 594.

Kyphoscoliosis in tetanus, 252.

L

Laasé, Christian F. L.: the health commissioner and the narcotic drug situation, 969.

Laboratories, army, future of, 108.

Laboratory type of physician, the, 409.

Lambert, Alexander: medicine, a determining factor in war, 984.

Landsman, Arthur A.: conditions which affect the occurrence of rectal diseases in infancy and childhood, 1089.

Langstroth, Francis Ward: the treatment of infections of the uterus and cervix, preliminary report of 75 cases, 1086.

Laparotomy through the ages, 652.

Laryngitis, tuberculous, the solar treatment of, 842.

Larnygoscopy, bronchoscopy and, relation of, to the field of general medicine, 304.

Lasegue's "délire de rêve," in a menstrual psychosis in a debile, 77.

Law, when is a man drunk in the eyes of the, 71.

League of Nations, need of a health clause in the, 881.

Left-handedness, 378.

Le Fort's work in surgery of the heart, 660.

Legislation, committee of the Medical Society of the State of New York on, report of, 844.

Legislative information bureau of, report of special committee of the Medical Society of the State of New York on the establishment of a, 845.

Leidy, Joseph: myristica (nutmeg) in the treatment of amebic dysentery, 354.

Leiner, Joshua H.: study of etiological factors bearing on the therapeutics of Bell's facial palsy, based on a review of 177 cases, 319.

Lemchen, B.: the mind and its abnormalities, 192.

Leprince, A.: nasal cauterization in the treatment of certain chronic affections (methods of Pierre Bonnier), 564.

Leprosy, recent Spanish-American investigations into, 176.
Lessons, medical and surgical, of the war, 639, 688, 734, 776, 821, 863, 904, 953, 999, 1053, 1091.
Leucemias, chronic action of the *x*-ray on the, 606; malignant growths which begin with, 294.
Leucocythemia lymphocytic, a case of Bence-Jones' albumosuria with, 206.
Levbarg, John J.: singers' and speakers' sore throat, 520.
Levin, Isaac: the cancer problem—a chapter in medicine, 551.
Liljestrand, G.: lung ventilation and artificial respiration, 1106.
Lice, one million persons killed by, 66.
Lille, children of, horrible fate of the, 374; the university of, during the German occupation, 329.

Meningococcus bronchopneumonia in influenza, 292; oxygen tension in its relation to the, 184.
Methylene blue, hexamethylenamine and, in grippe, 379.
Meyer, Alfred: influenza in a tuberculosis sanatorium, 592.
Meyer, Willy: a review of the evolution of thoracic surgery within the past fourteen years, 761, 800; etiology of thrombo-angiitis obliterans, 901; postoperative thoracic drainage, 773.
Microbism, latent, 831.
Migraines, prevention of certain, 1020.
Military organization and the treatment of the tuberculous soldier, 148.
Milk and the war, 126; brains and, 58; breast, too rich in fat, digestive disturbances due to, 665; commission of the Medical Society of the County of New York, report of, 86.
Mind and its abnormalities, the, 192.
Ministry of health bill, see *health.*
Missiles as emboli, a lecture on, 1018; in the tissues, a note on the variety and latency of organisms on, 85.
Mitchell, Clifford: a simple urine test for acidosis, 404; the iodine urine test for acidosis, 925.
Mitral lesion with cardiac asthenia, a case of, the ventricular weakness being demonstrable by the venous pulse, 33.
Mobilization after joint injuries, 571; immediate active, in the treatment of gunshot wounds of joints, 953, 999.
Mongolian idiocy and quadrupedal gait, 77.
Montgomery, Douglass W.: Rabelais, mention of the muscles, 636; seborrheic eczema of the lower lip, with deep central cracking, 438; sleep as mentioned by Rabelais, 277.
Montreal general hospital, annual meeting of the, 452; report of committee of sixteen of, 452.
Moral education, value of, 372.
Morgan's bacillus, the occurrence of, in chronic discharging wounds, 663.
Morphine habit, a new treatment for the, 420.
Morphinism, a study of the etiology and prophylaxis of relapse in, 1047.
Morris, R. T.: the two most important signs in chronic appendicitis, 55.
Moses, Henry Monroe: some experiences with U. S. A. base hospital No. 37, American expeditionary forces, 945.
Mosquito control in ponds, fishes and, 1061; eradication of the, and malaria control, 526; museum, a, 572; plague, Jerusalem freed, 950.
Mouth, some pathological conditions of the, and their treatment, 290.
Moving picture in teaching surgery (b), the moving picture with time and distance records, (c) the animated diagram in femoral hernia operation, remarks on the value of, 258, of Leo Mayer's operation, tendon transplantation for flat foot, 259; of Taylor's operation, tendon transplantation for flat foot, 259.
Muscle spasm, tonic, its significance as a clinical phenomenon, 375; Rabelais' mention of, 636.
Museum, a mosquito, 572; of medicine, national, suggestions for a, 482.
Musk, ad vocem, 447; in pneumonia, use of, not a scientific drug and subject to gross substitution, 356.
Mumps, meningitis encephalitis lethargica and, 619.
Mustard gas burns, 300.
Myocardial debility, diagnosis of, 1110.
Myocarditis, acute rheumatic, treatment of, 921.
Myoma uteri, see *Uterine myoma.*
Myopia, clinical considerations on, 798.
Myositis and arthritis, tonsillectomy in, 795.
Myotomy of the forearm in cases of digital contracture, 501.
Myristica (nutmeg) in the treatment of amebic dysentery, 354.
Myxedema, the heart in, 76.

N

N. C. A., neurocirculatory asthenia, 1068.
Narcosis, respiratory, possible benefits of, in preventing influenzal pneumonia, 657.
Nasal cauterization in the treatment of certain chronic affections (method of Pierre Bonnier), 564; obstruction in aviators, 376; origin, asthma of, 580.
Nasmith, G. G.: sanitation in war, 639.
Navy, Royal, vaccines and serums supplied to the, 290; U. S. annual report of the surgeon general, 245.
Necrosis, cell, and bacterial invasion in surgery, the role of 471 503.
Negligence army doctors accused of, 605; insufficient evidence of, 239, 566.
Neodiarsenol (Canadian neoarsphenamine), experiences with, 241 injections without ill effects, 637.

Neosalvarsan, anthrax cured by, 201.
the treatment of the pulmonary complications of influenza with calcium and, 207.
Nephrectomy, right-sided, followed by successful result, insufficient left kidney and, 1019.
Nephritides, cutaneous changes in the, 423.
Nephritis, chronic, clinical, functional and pathological observations on some cases of, 1075; from suppuration of the skin, 154; preliminary report on the presence of a filter-passing vaccine in certain diseases, with especial reference to trench fever, influenza, and, 420; trench, see *Trench nephritis*.
Nerves, injured, surgical treatment of, the mechanism of referred pain, hyperalgesia, and alcoholic injections for the relief of neuralgia, with suggestions for the, 1080; operations on the, and the late results, 33; peripheral, surgery of the, 937; peripheral, suture, 344; peripheral, war lesions of the, 904.
Nervous diseases, non-traumatic organic, in soldiers, 581.
Neuralgia, the mechanism of referred pain, hyperalgesia, and alcoholic injections for the relief of, with suggestions for the surgical treatment of injured nerves, 1080.
Neurasthenia as a self limited affection, 571.

Plague epidemic in India, 875.
Plasma of convalescent patients, treatment of influenzal pneumonia with, 83.
Plastic work, cutaneous, two procedures of, 422.
Pleural interventions, cerebral accidents following, 1010.
Pleurisy, initial serous, in tuberculosis, the genesis of, 207.
Pleuroperitonitis, primary, subacute tuberculous, 68.
Pneumococcus, the, and Italian bacteriologists, 26.
Pneumonia, acute empyema, acute appendicitis, pneumococcic peritonitis, their differential diagnosis, 102; and empyema in the late winter of 1917-1918, 673; and influenza, prophylactic inoculation in, 79; at base hospital No. 53, A. E. F., 599; constipation treatment of, 31; epidemic, in camps and eantonments in 1918, pathology of, 776; etiology of, 36, 887; etiology of, and its serum treatment, 719; frank, specifie treatment of, 163; gonococeus, report of a probable ease, 950; in infancy and childhood without physical signs, 1118; influenza and the dangers of secondary infection in the ward treatment of, 541; influenza, and pest pneumonia, some differences between, 1072; influenzal and pestous pneumonia, 379; influenzal, bacterial protein injections in, 616; influenza, case of acute mastoiditis with perisinus abscess, following operation performed under novocaine and morphine anesthesia, 323; influenzal, empyema following, 291; influenza,

in 1837, 330; influenzal, lung puncture in the treatment of, 973; influenzal, pathology of, 26; influenzal, possible benefits of respiratory narcosis in preventing, 657; influenzal, radiographic types of, 513; influenzal, serum treatment of, 253; influenzal, treatment of, 798; influenzal, treatment of with plasma of convalescent patients, 83; lobar, a year's experience in the Presbyterian hospital with special reference to the use of antipneumococcus serum, 895; of the recent epidemic, the clinical course and prognosis of the, 229; prophylactic inoculation against, a brief history and the present status of the procedure, 74; prophylactic vaccination against, 963; staphylococcus aureus, 696; treatment of the, 888; use of musk in, not a scientific drug and subject to gross substitution, 356; varioliform hemorrhagic exanthema during, a case of, 253.

Pneumoperitoneum, radiological diagnosis by means of, 798.

Pneumothorax, artificial, absorption of nitrogen and atmospheric air in, 501; artificial, treatment of advanced tuberculosis of the lungs by, 623; hypertensive traumatic eventration of the stomach into the left hemithorax with a clinical picture of, 378; spacing of injections in the maintenance of a, 32.

Poisoning, alleged, by minute doses of rhus toxicodendron, 788; arsenical, accidental death by, workmen's compensation, 105; fatal mercurial, following sublimate injections for the cure of varicose veins, 501; gas, in warfare, as study of the effects of so-called mustard gas upon the upper respiratory tract, 312; lead, ulnar nerve tenderness in, 205; with oil of chenopodium, 876.

Poisons, deaths by, in Cook County, Ill., during the period 1905-1917, 189; protein split product, relating to the possibility of, being formed in market milk, 186.

Poliomyelitis after-cure, 445; anterior, tendon transplantation in, 344; in the army, 501; recent studies in the physiology of tendons and their application to the operative treatment of, 428.

Politics, medicine and, 607.

Polycythemia, case of, treated successfully by radiotherapy, 1019; rubra, 578.

Polyglandular compensatory syndrome, a new, 1080.

Polyneuritis, acute febrile, note on a case of, 292.

Polyp, placental, 425.

Poock van Baggen, N. J.: breathing gymnastics for the marching soldier, 101.

Population, the diminishing, of England and Wales, 703.

Post-graduate scheme for London and the provinces, 927.

Post-influenzal immunity, 788.

Powers, C. A.: no fraternizing, 288.

Practitioner, demobilized, position of the 614; general, position of the, 289; of the future, the, 442.

Pregnancy and the postpartum state, observations on the severe anemias of, 251; cerebral hemorrhage complicating, 458; corpus luteum extract in the vomiting of, 982; influenza as a complication of, 979; occurrence of epidemic influenza in, 381.

Prenatal work in New York City, 285.

Prepuce as grafting material, the, 515.

Pre-war conditions, returning to, 576.

"Prison psychoses," etiology and mechanism of the, an opinion and some case studies, 6.

Prisoners, returning, 375.

Prohibition amendment, resolutions of Medical Society of the County of New York on, 246, 505; and after, 328; anti, resolutions, 527; in Canada, 158; measure, rigid, for New York, 155; opposed to, 369; sale of alcoholic drinks, 1014.

Prophylactic inoculation against pneumonia, a brief history and the present status of the procedure, 74; in pneumonia nad influenza, 79; typhoid fever occurring after, 376.

Prophylaxis in influenza, 617.

Prostatectomy, with its preparatory and postoperative treatment, 296.

Prostatic syphilis, 618.

Prostheses, arm, the formation of amputation stumps for voluntary movement of the, 162; cinematic amputations, the utilization of the muscles of a stump to actuate artificial limbs, 1004; of limbs, 501; the triceps muscle used as a motor force in, 293.

Prostitutes, mental deficiency in, a study of delinquent women at an army port of embarkation, 1017.

Prostitution, 1016.

Protein bodies, treatment of diseases of the blood and injections with, 1019; split product poisons, relating to the possibility of, being formed in market milk, 186.

Proteose therapy by the intravenous method, 1072.

Protoplasmic activation, non-specific, 1111.

Protozoon parasites, pathogenicity, cultivation, and reproduction of, 335.

Pseudoinfluenza, 654.

Psychasthenia, surgery and, 236.

Psychiatrical tests for all recruits, 326.

Psychic disturbances during influenza, 423.

Psychical treatment, war neuroses and, 880.

Psychogenous deafness, unconscious hearing in, 207.

Psychological study of stealing in juvenile delinquency, a, 463.

Psychology of interment, some remarks on the, based on the observation of prisoners of war in Switzerland, 929; of moral insanity, the, 619; of success in medicine, the, 633.

Psychoneuroses, the use of hypnotism in the treatment of, 601.

Psychopathy, memory (the mnemologic phenomena) in relation to intelligence, pedagogics and, 807.

Psychoses, digestive, a study of the, 753; menstrual, in a debile, Lasegue's "délire de rêve" in a, 77; postinfluenzal, 1068; prison, etiology and mechanism of the, an opinion and some case studies, 6; voluntary provocation of, 709.

Psychotherapy in influenza, 283.

Public health administration, course in, 573; affairs, education in, 705; and medical education, report of committee of the Medical Society of the State of New York on, 845; board of (German) and sanitary board, the object of and service rendered by the, 581; committee of the New York Academy of Medicine; report on the prevention of influenza, 516; democracy and, 124; education, report of Medical Society of the County of New York, 86; movement, international, Red Cross starts, 369; nurses, standardization plan for work of, 1064; officers, conference of, at Ottawa, 451; order, new, in England, 572; outlook and problems of, 1037; problems, new Governor outlines policy on, 69; regulations, new, for the control of epidemic disease, 449; report of committee of the Medical Society of the County of New York on, 85; report of special committee of the Medical Society of the State of New York to consider economic methods of caring for the, 845; service, annual report of the surgeon-general of the, for 1918, 155; service bill, 203; service, reconstruction program of the, 385; service starts campaign, 370; team-work in, 124; service, United States, program of, 121; service, united program of the, with relation to venereal control among the seamen of the merchant marine, New York harbor, 668; service, United States, war activities of the, 863; work, lipovaccines with special reference to, 122.

Pulmonary and cardiac cases for diagnosis, from the children's medical division of Bellevue hospital, 426.

Pupils, inequality of the, 25.

Purgation before and after abdominal section, 261.

Putti, Vittorio: the utilization of the muscles of a stump to actuate artificial limbs, 1004.

Q

Quacks, the lords and the, 1015.

Quadrupedal gait, Mongolian idiocy and, 77.

Quinine, action of, on the blood, 33; and arsenic, prevention of grippe by, 34; and aspirin, incompatibility of, 69; researches on the elimination of, 709; synthetics, nature of amaurosis from, 368.

R

Rabelais' mention of the muscles, 636; sleep as mentioned by, 277.

Rabies, epidemic of, in Paris, 582; in England, 744; increase of, 972; return of, 879; risk of, a dog landed in a bag, 927; treatment of, in England, 249.

Rabinowitsch, T.: the sale of alcoholic drinks, 1014.

Radiation, a new form of, from the human organism, 666.

Radiodiagnosis, a, of aneurysm of the abdominal aorta, 1111; of the consolidation of fractures, the, 379.

Radiographic types of influenzal pneumonias, 513.

Radiological diagnosis by means of pneumoperitoneum, 798; diagnosis with a distended abdomen, a new method, 207; procedure for abdominal diagnosis, a new, 798; symptom of gastric ulcer, a new, 118.

Radioscopy, 76.

Radiotherapeutic treatment of local hyperhidrosis with hard rays, 422.

Radiotherapy, a case of polycythemia treated successfully by, 1019; deep, in the gynecological clinic at Erlangen, particularly from the viewpoint of the dosage of the rays in the treatment of cancer, 665; in cancer; summary of six years, experience in the treatment of malignant diseases, 351.

Radium, analysis of fifty cases of uterine bleeding from causes other than malignancy or myoma treated by, 1077; demonstration at the Howard A. Kelly hospital, 299; in cancer of the upper air and food passages, 457; in the treatment of cancer, value and limitations of, 577; institute, the, 1015; its present status as surgery's adjunct, 1081; surgery versus, in the treatment of carcinoma of the bladder, 39; treatment, a note on personal experience in, 665; treatment, notes on, 538; treatment of myoma uteri with, 1077.

Rahmet Bey, H. T. M. K.: typhus fever, 48.

Railway men, strike of, 418.

Rat-bite fever, two cases treated with apparent success with a single dose of novarsenobenzol intravenously, 706.

Raynaud, syndrome of, 931.

Reaction, Gangi's, 24; defense, in pandemic grippe, 619.

Reconstruction program of the public health service, 385; work facilitated by the Red Cross, 326.

Recruits, effect of cardiac distress on the work of, 251; psychiatrical tests for all, 326.

Rectal diseases in infancy and childhood, conditions which affect the occurrence of, 1089.

Red Cross, American, children's bureau of, the work of, in Lyons, 114; congress at Cannes, 571, 655; 927, 1016; formulates peace program, 791; hospitals in Paris, evacuation of, 451; peace work of the, 880; relief for Poland, 928; relief work in France, 1116; relief work in Siberia, 1064; starts international public health movement, 369; starts world fight on typhus, 1063.

Redfield, Casper L.: brains and milk, 58.

Reeducation, functional, of the British soldier, 827; functional, of the French and American soldier, 829; of the blind soldiers, 545; of the blinded, 285.

Regeneration of joints, 1020; tissue, on, 456; tissue, in man, 1019.

Registrants, service, some notes from the examination of five thousand selected, 300.

Registration of births and deaths in Illinois, 126.

Rehabilitation in Canada, 821; of the disabled, conference on, 416, 567, 584, 621; of the disabled soldiers, a study in, 861; of the industrially crippled, commission for the, 878.

Rehousing and medicine, 71.

Reilly, T. F.: the clinical course and prognosis of the pneumonias of the recent epidemic, 229.

Renal changes, functional, in gynecology, 920; changes in dysentery, 709; colic, diagnosis of, 976.

Research laboratory, medical, at Mineola, the field of the, 210; narcotic, bureau of, 1103; scientific medical, and the people, 581.

Resection, bilateral, surgical treatment of exophthalmic and thyrotoxic goiter, with special reference to, 260.
Respiration, artificial, lung ventilation and, 1106.
Respiratory diseases, acute, among troops with especial reference to empyema, 195; narcosis, possible benefits of, in preventing influenzal pneumonia, 657; rate and rhythm, causes and consequences of disturbances of the, 796; tract as portal of entry for infectious diseases, 86; tract, chronic obstruction of the, and scoliosis, 1060.

Restoration, functional, training for lay workers in, 856.
Resuscitation work in a casualty clearing station, 796.
Retraction, congenital, of the ocular bulb, 207.
Rheumatic conditions, fibromyositis or, 1083; manifestation in children, erythema multiforme as a, 427.
Rhinoplastic surgery, idealism in, 900.
Rhus toxicodendron, alleged poisoning by minute doses of, 788.
Rickets, observations on the cause, 75; some late manifestations of, 525.
Roberts, H. H.: the therapeutic value of the spas and health resorts of America, 321.
Robinson, Beverley: bacillus or disease, which should be treated in influenza? 519; groping in medicine, 149; practical points in the treatment of fever, 818.
Robinson, E. P.: German physicians and American medicine, 1065.
